1Medicine, University of Southern California, Los Angeles, CA, United States, 2Preventive Medicine, University of Southern California, Los Angeles, CA, United States, 3Medicine, University of California San Diego, La Jolla, CA, United States, 4Medicine, University of Colorado at Denver, Denver, CO, United States, 5Medicine, University of California San Diego, La Jolla, CA, United States, 6Psychiatry, University of California San Diego, La Jolla, CA, United States, 7Neurology, University of California San Diego, La Jolla, CA, United States, 8Neurology, University of California San Diego, La Jolla, CA, United States, 9Psychiatry, University of California San Diego, La Jolla, CA, United States

Background: Waist circumference (WC) correlates with the severity of HIV-associated neurocognitive disorder (HAND) that still occurs in ~50% of patients. The mechanism for this relationship is unknown. We postulated that patients with abdominal obesity have increased levels of systemic and CNS immuno-inflammatory mediators that cause neurocognitive impairment (NCI).

Methodology: To explore this hypothesis, we tested stored plasma and CSF from 152 HIV+ patients (151 on cART) from CHARTER study visits with: (a) WC measurements, (b) standardized, comprehensive neuromedical and neurocognitive assessment, c) no CNS confounding conditions (e.g. major trauma, stroke), and (d) plasma HIV RNA <1,000c/ml. Levels of biomarkers in plasma (IL-6, sCD163, and sCD14) and CSF (sCD40L, sTNFrII, MCP-1, sICAM, and MMP-9) were measured. NCI was assessed by a standardized battery of 7 test domains of cognition. The global deficit score (GDS) was calculated for each subject after adjustments for their age, race/ethnicity, and education and a value ≥0.5 defined NCI. Correlational and pathway analyses were performed to explore the relationships of WC as the primary predictor and the biomarkers as mediators in models of NCI.

Results: WC and plasma levels of IL-6 correlated with GDS (WC: rho=0.21, p=0.009 and IL-6: rho=0.17, p=0.04). The correlation of WC with GDS was strongest in participants with the highest tertile of IL-6 levels (rho=0.39, p=0.005) compared to those with the lowest tertile (rho=-0.07, p=0.65). IL-6 only correlated with GDS if WC ≥99cm. For subjects with the highest tertile of CSF sCD40L, a marker of CNS macrophage and microglial activation, the relationship of IL-6 to GDS was greater (rho=0.60, p<0.0001). In subjects with GDS measures at ≥3 visits (6 month intervals) within ±1 year of the index visit, higher IL-6 levels predicted a positive slope of GDS (rho=0.28, p=0.06), implying worsening NCI. A separate Pathway analysis based on regression coefficients produced a strong, integrated model (highly consistent with the data) for subjects in the highest tertile of CSF sCD40L, which showed that a) WC directly affected GDS, b) the effects of WC on GDS were also mediated by IL-6 and c) plasma sCD14, a microbial translocation and monocyte activation marker, positively affected the relationship of WC and IL-6 to GDS.

Conclusions: Abdominal obesity was related to cognitive impairment in well-controlled HIV+ patients with high levels of systemic inflammation (IL-6) and CNS immune activation (sCD40L). These data are consistent with our postulate that abdominal fat releases mediators that drive systemic inflammation and CNS immune activation thereby worsening NCI. These effects may be amplified by monocyte activation (sCD14) due to intestinal translocation of bacterial products.

489 Blood Cell Indices and Neurocognitive Impairment in the HAART Era: A CHARTER Study
Asha R. Kallianpur1, Quan Wang2, Peilin Jia2, Justin C. McArthur3, Susan Morgello4, Ann C. Collier5, Benjamin B. Gelman6, David B. Clifford7, J. Allen McCutchan8, Igor Grant9, the CHARTER Study Group
1Genomic Medicine, Lerner Research Institute, Medicine Institute, Cleveland, OH, United States, 2Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN, United States, 3Neurology, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 4Neurology/Pathology, Mount Sinai School of Medicine, New York, NY, United States, 5Medicine/Allergy and Infectious Diseases, University of Washington, Seattle, WA, United States, 6Pathology, University of Texas Medical Branch, Galveston, TX, United States, 7Neurology, Washington University School of Medicine, St Louis, MO, United States, 8Medicine/Infectious Diseases, University of California San Diego, La Jolla, CA, United States, 9Psychiatry, University of California San Diego, La Jolla, CA, United States

Background: Red blood count (RBC), mean cell volume (MCV), mean cell hemoglobin (MCH), and hemoglobin (Hgb) levels reflect both iron status and changes due to inflammation. Since iron is critical for maintenance of mitochondrial energetics and brain function, and anemia was a risk factor for HIV-associated dementia in the pre-HAART era, we examined the relationship of these indices to risk of neurocognitive disorders (HAND) in the HAART era.

Methodology: We evaluated cross-sectional associations of red cell indices, and time-dependent associations of Hgb, with HAND in the CNS HIV Antiretroviral Therapy Effects Research (CHARTER) study, a U.S.-based cohort study of neurological complications in the HAART era. CHARTER study subjects underwent standardized neurocognitive and neuromedical assessments, including RBC, MCV, MCH, and Hgb. HAND was defined by Frascati criteria (absence of neuromedical confounds, at least two impaired cognitive domains, and combined self-report and performance-based assessment of functional impairment). Adjusted β-coefficients (β), odds ratios (OR), or hazard ratios (HR) and their 95% confidence intervals (CIs) were estimated for RBC, MCV and MCH associations with HAND using multivariable (and for Hgb, also time-dependent) regression to adjust for age, race, ethnicity, HAART, zidovudine (ZDV) use, CD4 nadir, plasma viral load, and wide-range achievement test score at entry.

Results: Neurocognitive performance data, red cell indices, and Hgb were available in 1235 CHARTER enrollees [median age 43 years, 23% women, med. CD4 nadir 181 cells/mm3, 864 (70%) on HAART, 17% ZDV use]. HAND was present in 584 subjects (43%) at entry. MCV and MCH were associated with HAND in unadjusted analyses [OR 1.02 (p=0.003) and OR 1.05 (p=0.005)], respectively and adjusted analyses [OR 1.02 for MCV (2% increase in risk per femtoliter rise in MCV), p=0.02 and OR 1.04 for MCH (4% increase in risk per picogram/cell rise in MCH, p=0.02, respectively). MCV and MCH were also associated with cognitive impairment (Global Deficit Score (GDS)) as a continuous measure [β for MCV and MCH were 0.006 (p<0.001) and 0.015 (p<0.01), respectively]. Hgb was inversely associated with continuous GDS (β = -0.054 (p<0.01) and anemia was associated with cognitive impairment (GDS≥0.5) over 18 to 36 months of follow-up (adjusted HR 1.21, p<0.01). Mild neurocognitive disorder was associated with RBC, MCV, and MCH [OR 0.57 (p=0.01), OR 1.03 (p=0.04), and OR 1.10 (p<0.01), respectively], and dementia was associated with MCV [OR 1.10 (p<0.05)].
Conclusions: Red cell indices and anemia, which as markers of iron metabolism are intimately linked to inflammation, oxygen delivery, and mitochondrial function, remain associated with HAND susceptibility in the HAART era.

490 CNS Immunocaution in HIV Patients On ART With HIV-Associated Mild Neurocognitive Impairment

Arvid Eden1, Donald R. Franklin1, Dietmar Fuchs1, Igor Grant2, Scott Letendre3, Thomas Marcotte4, Staffan Nilsson4, Richard W. Price1, Henrik Zetterberg1, Magnus Gisslén6
1University of Gothenburg, Gothenburg, Sweden, 2University of California San Diego, La Jolla, CA, United States, 3Innsbruck Medical University, Innsbruck, Austria, 4Chalmers University of Technology, Gothenburg, Sweden, 5University of California San Francisco, San Francisco, CA, United States

Background: Even in patients responding well to current antiretroviral therapy (ART), HIV-associated neurocognitive disorders (HAND) remain prevalent. However, it is unclear if neuronal damage continues despite effective suppression of HIV-1. The light subunit of the neurofilament protein (NFL) is a component of myelinated axons, and elevated concentrations in cerebrospinal fluid (CSF) are a sensitive marker of ongoing axonal injury in HIV-associated dementia (HAD). To investigate if milder forms of neurocognitive impairment - asymptomatic neurocognitive impairment (ANI) and minor neurocognitive disorder (MND) - are associated with ongoing neuronal damage, we analyzed CSF NFL in a well characterized cohort of virally suppressed subjects on ART with or without ANI/MND.

Methodology: In a cross-sectional analysis, subjects on ART with plasma HIV-1 RNA <50 c/ml without significant confounding conditions (e.g., current substance dependence) were identified from longitudinal studies (CHARTER and HNRC). Standardized neurocognitive performance (NP) testing was performed. Subjects were classified as NP-normal (NPN) or NP-impaired (ANI/MND) based upon demographically-adjusted norms. Subjects were selected to yield approximately equal samples of NPN, ANI, and MND. CSF concentrations of NFL were measured by an enzymatic 2-site quantitative immunoassay (UmanDiagnosics, Umeå, Sweden). CSF neopterin was measured by ELISA. Continuous variables were log10 transformed where appropriate. For two group comparisons, Mann-Whitney U-test was used. The relationship between CSF NFL levels and age in the two groups were analyzed with a linear mixed effects model. Correlations were calculated using Pearson correlation coefficients test.

Results: 100 (91% male) subjects were included in the analysis, 29 NPN and 71 with ANI/MND (ANI=38; MND=33). Median (IQR) age was 47 (41-54) years, with current CD4+ 524 (359-771) and nadir 72 (10-224) x106 cells/l. No statistically significant difference was found in NFL between the NPN and ANI/MND groups. We found no correlation between CD4 cell count or CD4 nadir and NFL, however CSF neopterin was significantly correlated to NFL in the whole study population (r=0.21; p=0.035) and CSF neopterin was higher in the ANI/MND group (median 7.3, IQR 4.9-12 nmol/l) than in the NPN group (median 4.8, IQR 4.7-7.4 nmol/l) (p<0.01).

Conclusions: In this cross sectional analysis we found no difference in NFL in subjects with ANI/MND compared to subjects without neurocognitive impairment. Interestingly, CSF neopterin was higher in the ANI/MND group indicating an association between increased intrathecal immunoactivation and neurocognitive impairment in patients on ART.

491 CNS Inflammation During Treatment-Induced Viral Suppression

Julia Peterson1, Sheila M. Keating2, Viktor Dahl2, Phillip J. Norris3, Sarah Palmer4, Dietmar Fuchs5, Henrik Zetterberg6, Magnus Gisslén6, Richard W. Price1
1Neurology, University of California San Francisco, San Francisco, CA, United States, 2Blood Systems Research Institute, San Francisco, CA, United States, 3Karolinska Institute, Stockholm, Sweden, 4Westmead Millennium Institute for Medical Research and University of Sydney, Westmead NSW, Australia, 5Innsbruck Medical University, Innsbruck, Austria, 6 Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Background: Several studies have shown that antiretroviral therapy (ART) reduces the intrathecal inflammation characteristic of HIV infection, but the extent and character of any residual central nervous system (CNS) inflammation that may persist despite clinical viral suppression or in the presence of very low-level viral detection is not well characterized. This study measured a panel of inflammatory biomarkers in cerebrospinal fluid (CSF) in a group of treatment-suppressed subjects in which low-level virus was also measured by single copy assay (SCA) in both CSF and paired plasma samples.

Methodology: Archived samples of CSF and plasma from 45 HIV-positive subjects with >2 years of treatment and viral suppression (<40 HIV RNA cpm) were included, with repeated sampling of 16 of the subjects so that a total of 76 sample pairs were included. Both CSF and blood viral load was further evaluated using the sensitive SCA method to measure virus levels down to <0.3 cpm. Using multiplex bead array or ELISA, we measured CSF IL-6, TNF-α, IP-10, MCP-1, MMP-9, sVCAM, sCD14, TIMP-1, sCD163, and neopterin in CSF in this sample set along with neurofilament light chain protein (NFL) to assess neural injury. Biomarker results in these samples were compared to CSF in 21 age-matched HIV-uninfected controls. Additionally, the CSF samples with <0.3 RNA cpm (SCA-) were compared to those with >0.3 cpm (SCA+) to see if detection of low level CSF virus was associated with increased intrathecal immunoactivation and neuronal damage in patients on ART.

Results: The treated-suppressed subjects had: documented infection for a median of 8.1 years; plasma viral suppression by clinical assay for 2.8 years; median age 48 years; median CD4+ T cell count at sampling of 613 cells/μL with nadir of 193 cells/μL. HIV-1 RNA was detected by SCA in 6% of the subject’s CSF and in 20% of the subject’s plasma at baseline. Of the CSF biomarkers assessed, significant elevations in the treated-suppressed group compared to HIV- controls were detected in CSF TNF-α (p<0.0001) and CSF sCD163 (p=0.0001). There were no significant differences between treated-suppressed and HIV- subjects in other inflammatory biomarkers or NFL. When SCA- and SCA+ specimens were directly compared, significant elevations in the SCA+ group were detected only in neopterin (p=0.0085). Other inflammatory markers and NFL did not significantly differ between subjects with or without low level CSF virus detected by SCA.

Conclusions: While ART that suppresses CSF HIV RNA below clinical detection levels also reduces local immune activation, some subjects exhibit persistent, though restricted low-level, inflammation that associates with virus detected by SCA. The pathobiology and clinical consequences of these findings merit further study.
CSF Viremia and Inflammatory Markers in Pts With NCI On TDF/FTC/EFV and After Switch To ABC/3TC/MVC

Juan M. Tiraboschi1, Jose Muñoz-Moreno2, MC Puetas2, Carlos Alonso3, Anna Prats-Paris1, Elena Ferrer1, Nerea Rozas1, Marga Maso-Serra1, Javier Martinez-Picado3, Daniel Podzamczer1

1HIV Unit, Infectious Disease Service, Hospital Universitari de Bellvitge, Barcelona, Spain, 2Fundació Lluita contra la SIDA - Unitat de VIH, Hospital Universitari Germans Trias i Pujol, Barcelona, Spain, 3Institut de Recerca de la SIDA IrsiCaixa, Barcelona, Spain, 4Complex Sanitari Santa Tecla, URV, Tarragona, Spain

Background: A low-level viremia in cerebrospinal fluid (CSF) while on cART may promote local immune activation, and inflammatory responses. The aim of this study was to evaluate HIV-1 viral load (VL) and inflammatory markers in CSF, as well as the impact on neuropsychological performance in patients with neurocognitive impairment (NCI) while receiving TDF/FTC/EFV and after switching to a regimen with enhanced CNS penetrability.

Methodology: Cross sectional and longitudinal study. HIV+ virologically suppressed pts on TDF/FTC/EFV with documented NCI were included and switched to ABC/3TC/MVC. Pts with NCI due to a cause other than HIV were excluded. A trained neuropsychologist performed a 7-domain neuropsychological assessment at baseline and week 48. CSF and blood samples were taken at BL and week 24-36. HIV-1 RNA in plasma (LOD 40 c/ml) and CSF (LOD 2.5 c/ml) were determined by real-time PCR. Inflammatory markers in CSF were measured by ELISA. Baseline inflammatory markers were compared with already published data of healthy subjects.

Results: 70 pts receiving TDF/FTC/EFV were tested, 12 of them had documented NCI, CCR5 tropic virus determined from proviral HIV-1 DNA, and lacked the HLA-B*57:01 haplotype. Median (IQR) age was 54 (33-65) years, CD4 T count 529 (483-576) cells/μl, and nadir CD4 T cells 178 (15-482) cells/μl. Median time on TDF/FTC/EFV was 42.5 (15-86) months and time with undetectable VL 78 (24-144) months. At BL, 8 pts had CSF VL between 2 and 40 c/ml while suppressed in blood plasma and all of them had increased neopterin and MCP-1 levels.

Eight patients had a complete assessment at follow-up, a second lumbar puncture (LP) was performed in 9 pts a median of 36 (24-36) weeks after baseline, and 9 had a neuropsychological assessment at week 48. One pt was lost, a non-compliant pt presented viral failure at week 36, one did not accept a second LP, and another one a second NC test.

Conclusions: Most pts with NCI while receiving TDF/FTC/EFV had low-level viremia in CSF and/or increased inflammatory markers. After switching to a regimen with better CNS penetration, an improvement in neuropsychological tests was observed, as well as a significant reduction in TNFa concentration in CSF, but with viral suppression in only 2 pts. Larger studies are needed to confirm if there may be a benefit from switching from TDF/FTC/EFV to ABC/3TC/MVC and to elucidate if this improvement is related to either a reduction in toxicity or to a better antiviral activity in CNS, or both.

Rifapentine Once-Weekly Dosing Effect On Efavirenz, Emtricitabine and Tenofovir PKs

Christine Farenc1, Severine Doroumian1, Cathy Cantallouble1, Laurent Perrin2, Virginie Esposito3, Isabelle Cierien-Puiseux4, Xavier Boulenc1, Marilyn Maroni4

1Disposition Safety Animal Research, Sanofi, Montpellier, France, 2Clinical Exporatory Pharmacology, Sanofi, Montpellier, France, 3Clinical Exploratory Pharmacology, Sanofi, Paris, France, 4Access To Medecines, Sanofi, Paris, France

Background: A large Phase 3 trial (Prevent TB TBTC Study 26) indicated that rifapentine (RPT) plus isoniazid (900 mg each once a week) for 3 months was effective and well tolerated for the treatment of latent tuberculosis infection (TB). RPT, an inducer of both CYP3A4 and CYP2B6, is expected to affect the efavirenz (EFV) PK which is a potential concern for Drug-Drug Interaction if RPT is administered in HIV infected subjects under treatment with EFV-based antiretroviral therapy (ART). Interaction towards emtricitabine (FTC) and tenofovir cannot not be ruled out, since these compounds are substrates of transporters and rifamycins, such as RPT may lead to up-regulation of transporters via PXR activation. In this context, a clinical interaction study between RPT and ATRIPLA™ fixed-dose combination of EFV 600 mg, FTC 200 mg, and tenofovir disoproxil fumarate (TDF) 300 mg, was conducted.
Methodology: 12 HIV+ TB free subjects with a CD4 > 350 cells/mm³ and viral load < LOQ, receiving ATRIPLA™ as background therapy, were enrolled in an open-label, single sequence, two periods, non-randomized study. PK interactions were evaluated after single and repeated administration of RPT 900 mg once weekly. In order to evaluate the maximal effect of induction, study design was optimized using a Physiological Based PK model. Blood samples were collected over 24-h post-dose of ATRIPLA™, before RPT administration, following the first RPT dosing and 38 h after the 3rd RPT dosing. Plasma concentrations were quantified by LC/MS. PK parameters were calculated by a non-compartmental analysis. Estimates of Cmin, Cmax and AUC0-24 geometric mean ratios (GMR) (with versus without RPT) with 90% CIs for EFV, FTC and tenofovir were obtained using linear mixed effects model for single and repeated administration of RPT.

Results: GMR and 90%CIs are presented in table 1

Conclusions: Steady state exposures of EFV, FTC and tenofovir in HIV infected subjects, with and without RPT co-administration were generally comparable. However, a single administration of RPT, increased Cmax of tenofovir by 23% while repeated weekly RPT administration resulted in a modest reduction (15%) in tenofovir Cmin and both EFV Cmin and AUC0-24. Overall, the co-administration of ATRIPLA™ with RPT was well tolerated and, no clinically significant modifications of CD4 cell counts or viral loads were observed.

494 Relationship Between Efavirenz Trough & CYP2B6 Genotypes With Rifampin-Based TB Therapy in STRIDE

Anne Luetkemeyer1, Susan L. Rosenkranz2, Darlene Lu1, Beatrix Grinsztejn1, Jorge Sanchez1, Michael Ssemmanda6, Ian Sannie7, Helen McIlleron8, Diane Havlir1, David Haas9, ACTG A5221 & A5243 Study Teams

1HIV/AIDS Division, San Francisco General Hospital, University of California San Francisco, San Francisco, CA, United States, 2Center for Biostatistics in AIDS Research, Harvard School of Public Health, Boston, MA, United States, 3HIV/AIDS Division, Center for Biostatistics in AIDS Research, Harvard School of Public Health, San Francisco, CA, United States, 4Instituto de Pesquisa Clinica Evandro Chagas, Fundacao Oswaldo Cruz, Rio de Janeiro, Brazil, 5Asociacion Social Impacta Salud y Educacion, Lima, Peru, 6Joint Clinical Research Center, Kampala, Uganda, 7Clinical HIV Research Unit, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa, 8Division of Clinical Pharmacology, University of Cape Town, Cape Town, South Africa, 9Vanderbilt University School of Medicine, Nashville, TN, United States

Background: Rifampin (RIF) induces cytochrome P450 (CYP) isoforms, which can lower plasma EFV exposure. However, in STRIDE, RIF-containing tuberculosis therapy was associated with increased EFV Cmin. As CYP2B6 polymorphisms predict EFV exposure, we conducted a nested pharmacogenomics study to evaluate EFV Cmin by CYP2B6 metabolizer status in STRIDE participants.

Methodology: EFV Cmin was measured by HPLC (LOQ = 0.1 μg/mL) in samples obtained 20-28 hours post-dose following no missed doses in prior 3 days (self report). CYP2B6 genotyping was by MassARRAY iPLEX Gold (Sequenom, Inc). Metabolizer status was defined by three CYP2B6 polymorphisms; 15582C→T, 516G→T, and 983T→C as follows: extensive = CC-GG-TT or CT-GG-TT; intermediate = TT-GG-TT, CC-GT-TT, CC-GG-TT, CT-GG-TT; or CT-GT-TT; slow = CC-TT-TT, CC-GT-TC, or CC-GG-CC. Only subjects who consented for genetic testing under protocol A5243 were included.

Figure: Each line represents on- & off-RIF EFV Cmin for each subject. Bolded black lines = group medians
Poster Abstracts

495 Concentrations of Nevirapine or Efavirenz On and Off Anti-Tuberculosis Therapy (ANRS12214)
Nilesh Bhatt1, Elisabeth Baudin2, Bindiya Meggi1, Carlota Silva1, Valerie Furlan1, Aurelie Barral-Tran2, 3, Maryline Bonnet1, Anne-Marie Taburet3
1Instituto Nacional de Saúde, Ministry of Health, Maputo, Mozambique, 2Clinical Research Department, Epicentre, MSF, Paris, France, 3Clinical Pharmacy, Hospital Bicêtre, Paris-Sud University, Kremlin Bicêtre, France

Background: The randomized ANRS12146-CARINEMO clinical trial enrolled Mozambican HIV-tuberculosis (TB) coinfected patients with the objective to compare efficacy and tolerance of nevirapine (NVP) or efavirenz (EFV)-based antiretroviral (ARV) therapy. Non inferiority of NVP could not be demonstrated. A substudy was designed to compare concentrations (conc.) of NVP or EFV during coadministration with TB treatment and after discontinuation.

Methodology: Sixty-two patients agreed to participate to the ANRS12214 substudy. They received rifampicin and isoniazid for six months combined to ethambutol and pyrazinamide during the first two months. ARVs were initiated between 4 and 6 weeks of antiTB treatment and patients were randomized to receive either NVP200mg bid or EFV600 mg qd both combined with lamivudine and stavudine. Blood samples for pre-dose conc. of NVP and mid-dose conc. of EFV were collected at weeks (wk) 1, 2, 3, 4 and 12 after ARVs initiation when patients were on TB treatment and at wks 36 and 48 after cessation of TB treatment. NVP and EFV were assayed by HPLC (limit of quantification 50ng/mL for EFV and 25 ng/mL for NVP, between run variability <12%). Mixed models were used to analyse the change in log-transformed conc. with time, time being a fixed effect in the model.

Results: Median age and weight of patients (60% male) at inclusion were 34 years and 52 kg, respectively. They had a median CD4 of 100 cells/μL and median HIV-RNA of 5.6 log10 copies/mL. Twelve hour-post dose conc. of NVP and mid-dose conc. of EFV were collected at weeks (wk) 1, 2, 3, 4 and 12 after ARVs initiation when patients were on TB treatment and at wks 36 and 48 after cessation of TB treatment. NVP and EFV were assayed by HPLC (limit of quantification 50ng/mL for EFV and 25 ng/mL for NVP, between run variability <12%).

Conclusions: In a subset of STRIDE subjects genotyped for CYP2B6, slow metabolizer status was associated with high EFV concentrations off-RIF; 50% had even higher EFV Cmin on-RIF. This suggests that increased EFV Cmin with rifampin is driven in part by slow metabolism genotypes.

496 Pharmacokinetics of Raltegravir 400 vs 800 mg BID With Intermittent Rifampicin Dosed Thrice Weekly
Helen E. Reynolds1, Deirdre Egan1, Laura Else1, Mas Chaponda2, Ales Chrdle2, David J. Back1, Saye H. Khoo1
1University of Liverpool, Liverpool, United Kingdom, 2Royal Liverpool University Hospital, Liverpool, United Kingdom

Background: ‘DOTS’ strategies involve directly observed medication intake to maximise adherence to antituberculous therapy (ATT), utilising either daily, or thrice-weekly rifampicin (RIF)-based regimens. In HIV-TB coinfection, raltegravir (RAL) represents an alternative antiretroviral for patients with efavirenz resistance or intolerance. As drug interactions with intermittent RIF regimens have not been studied we evaluated the effect of thrice-weekly RIF on pharmacokinetics (PK) of RAL dosed at 400mg and 800mg bid.
Methodology: Open-label, 3 phase healthy volunteer study. Subjects received RAL 400 bid for 5 days, then 33 days of RAL (400mg bid) + RIF (900mg thrice weekly; all subjects >50kg), then 5 days of RAL (800mg bid) + RIF as above. Blood samples were collected at 0, 1, 2, 4, 6, 8, 12h post-dose and RAL determined by validated LC-MS/MS. PK parameters were estimated (nonparametric; WinNonLin). The primary endpoint was change in RAL AUC(0-12h), secondary endpoints were change in Cmin, Cmax and tolerability of the combination. Putative efficacy targets for RAL have been proposed as 15ng/ml (MEC1- in vitro IC50 in presence of 50% HSA) and 21ng/ml (MEC2- the upper bound of the lowest quartile of QDMRK, associated with blunted therapeutic response).

Results: Of 18 healthy volunteers recruited, PK data were available for 16 (1 subject was excluded for asymptomatic rise in creatinine kinase which resolved 17d after stopping RAL, another for taking the wrong dose of RIF). PK data are shown below:

Conclusions: Following co-administration of thrice weekly RIF, the AUC and Cmax of RAL were not significantly lowered with 400mg bid dosing, but were significantly greater with 800bid dosing; the combination was well-tolerated. In contrast, when coadministered with RIF, C12h of RAL was reduced by 40% with 400mg bid dosing, although this impact was not seen with 800mg RAL. Importantly, a significant proportion of subjects taking RAL 400mg bid (4/16) had C12h at/below MEC2. Similar findings were observed with RAL + daily RIF in patients (the REFLATE study) suggesting RIF induction of RAL is comparable between daily and intermittent RIF. In the absence of definitive clinical efficacy data to suggest otherwise, doses of RAL 800mg bid with thrice-weekly RIF are well tolerated and yield higher AUCs and comparable C12 compared to RAL alone.

PI Pharmacokinetics of Faldaprevir and Antiretrovirals in Patients With HIV/HCV Coinfection

Jürgen K. Rockstroh1, Marc-Antoine Valantin2, Josep Mallolas3, Massimo Puoti4, Juan Antonio Pineda5, Patrick Ingiliz6, Marina Núñez7, Fenglei Huang8, Richard Vinisko9, Douglas Dieterich9

1Department of Medicine I, University of Bonn, Bonn, Germany, 2Service des Maladies Infectieuses et Tropicales, Hôpital Pitié-Salpêtrière, Paris, France, 3Hospital Clinic-University of Barcelona, Barcelona, Spain, 4Department of Infectious Diseases, AO Ospedale Niguarda Ca’ Granda Milano, Milan, Italy, 5Unit of Infectious Diseases and Microbiology, Hospital Universitario de Valme, Seville, Spain, 6Medical Center for Infectious Diseases, Berlin, Germany, 7Wake Forest University Health Sciences, Winston-Salem, NC, United States, 8Boehringer Ingelheim Pharmaceutical, Inc, Ridgefield, CT, United States, 9Mount Sinai Medical Center, New York, NY, United States

Background: Faldaprevir (FDV) is a potent, once-daily HCV NS3/4A protease inhibitor being developed for the treatment of HCV genotype 1 infection in mono-infected patients and HIV co-infected patients. In studies in healthy volunteers, FDV increased raltegravir (RAL) exposure by about 2.5-fold and had no substantial effect on the pharmacokinetics (PK) of darunavir/ritonavir (DRV/r), efavirenz (EFV), or tenofovir (TDF). We present here an interim analysis of PK interactions between FDV and antiretrovirals (ARV) in STARTVerso4, an ongoing Phase 3 study assessing the efficacy and safety of FDV + pegylated interferon alfa-2a/ribavirin (PR) in HIV patients co-infected with HCV genotype 1.

Methodology: HCV/HIV co-infected patients on a DRV/r- or atazanavir/r (ATV/r)-based ARV regimen were assigned to FDV 120 mg QD; those on EFV were assigned to FDV 240 mg QD. The FDV dose for patients on other ARV regimens was randomly assigned. Pre-dose blood samples were collected in the morning on Day 1 (baseline) and Weeks 2, 4, 8, 24, and 36 for ARVs and on Day 1 and Weeks 1, 2, 4, 8, and 12 for FDV. Plasma drug concentrations were determined by validated HPLC-MS/MS.

Results: Of 308 treated patients, 297 were receiving ARV therapy (ATV/r [n=12], DRV/r [n=55], EFV [n=84], RAL [n=143], or other ARV [n=3]). In the FDV 120 mg group, pooled FDV trough concentrations were higher with DRV/r than RAL (gMean C12h in 2010 ng/ml vs. 1390 ng/ml, respectively). In the
FDV 240 mg group, pooled FDV trough concentrations were lower with EFV than with RAL (gMean C\text{pre,ss} 1250 ng/ml vs. 4840 ng/ml, respectively). FDV had no effect on EFV C\text{pre} levels and reduced DRV C\text{pre,ss} levels by about 50% (Table). RAL C\text{pre,ss} was similar with or without FDV treatment. A sub study with intensive PK sampling showed no effect of FDV on ATV PK parameters. The adverse event profile was consistent with historical data on PR treatment and HAART in HIV/HCV co-infected patients.

**Conclusions:** In this interim analysis of data from STARTVerso4, consistent with observations from studies in healthy volunteers, there were no clinically relevant drug interactions with FDV on studied ARVs in patients co-infected with HIV and HCV.

**Pharmacokinetic Interactions Between the HCV NS5A Inhibitor MK-8742 and Efavirenz**

Wendy Yeh\textsuperscript{1}, William Marshall\textsuperscript{1}, Eric Mangin\textsuperscript{1}, Xiaobi Huang\textsuperscript{1}, Yali Zhu\textsuperscript{1}, Susanne Langley\textsuperscript{1}, Patricia James\textsuperscript{3}, Stephen Youngberg\textsuperscript{2}, Joan Butterton\textsuperscript{1}

\textsuperscript{1} Merck, Sharp and Dohme, Whitehouse Station, NJ, United States; \textsuperscript{2} Celerion, Lincoln, NE, United States

**Background:** MK-8742, an inhibitor of the hepatitis C virus (HCV) NS5A protein, is being developed for the treatment of HCV infection. HCV infection is a major cause of morbidity and mortality in patients coinfected with human immunodeficiency virus-1 (HIV) and HCV. This study evaluated the pharmacokinetic interactions and safety of MK-8742 coadministered with either TDF, RAL, or EFV in healthy subjects.

**Methodology:** This was a 3-part, open-label, fixed-sequence study in 30 healthy adult male and female volunteers, ages 19-55 years. In Part 1, 10 subjects received oral doses of 300 mg TDF once daily for 7 days followed by a 7-day washout, 50 mg MK-8742 once daily for 8 days, and then 50 mg MK-8742 and 300 mg TDF coadministered once daily for 7 days. In Part 2, 10 subjects received a single oral dose of 400 mg RAL followed by a 4-day washout, a single oral dose of 50 mg MK-8742 followed by a 7-day washout, and then a single oral dose of 400 mg raltegravir coadministered with a single oral dose of 50 mg MK-8742. In Part 3, 10 subjects received oral doses of 50 mg MK-8742 once daily for 7 days followed by a 7-day washout, oral doses of 600 mg EFV once daily for 14 days, and then oral doses of 50 mg MK-8742 and 600 mg EFV coadministered once daily for 7 days. Safety assessments included electrocardiograms, vital signs, clinical laboratory tests, physical examination, and adverse event monitoring.

**Results:** Coadministration of MK-8742 with either TDF, RAL or EFV was safe and generally well-tolerated. In Part 1, multiple oral doses of MK-8742 increased the steady-state AUC\textsubscript{0-24h} of TDF with (TDF+MK-8742/TDF) geometric mean ratio (GMR) [90% confidence intervals (CIs)] of 1.34 [1.23, 1.47]. Multiple oral doses of TDF did not meaningfully alter the steady-state AUC\textsubscript{0-24h} of MK-8742 with (MK-8742+TDF/MK-8742) GMR of 0.93 [0.82, 1.05]. In Part 2, 10 subjects received a single oral dose of 400 mg RAL followed by a 4-day washout, a single oral dose of 50 mg MK-8742 followed by a 7-day washout, and then a single oral dose of 400 mg raltegravir coadministered with a single oral dose of 50 mg MK-8742. In Part 3, 10 subjects received oral doses of 50 mg MK-8742 once daily for 7 days followed by a 7-day washout, oral doses of 600 mg EFV once daily for 14 days, and then oral doses of 50 mg MK-8742 and 600 mg EFV coadministered once daily for 7 days. Safety assessments included electrocardiograms, vital signs, clinical laboratory tests, physical examination, and adverse event monitoring.

**Conclusions:** MK-8742 concentrations decreased following coadministration with EFV, likely as a result of CYP3A4 induction by EFV. Co-administration of MK-8742 and either RAL or TDF in healthy volunteers did not result in clinically meaningful drug-drug interactions.
### Effect of Faldaprevir On Atazanavir Pharmacokinetics in Patients With HIV/HCV Coinfection

**Mark Nelson**1, Keikawus Arastéh2, Mantra K. Jain3, Vicente Soriano4, José Valdez Madruga5, Juvencio Furtado6, Manuel Battegay7, Fenglei Huang8, Montserrat Manero9, Douglas Dieterich10

1Chelsea and Westminster Hospital, London, United Kingdom, 2EPIMED/Vivantes Auguste-Viktoria-Klinikum, Berlin, Germany, 3UT Southwestern Medical Center, Dallas, TX, United States, 4Hospital Carlos III, Madrid, Spain, 5Centro de Referencia e Treinamento DST/AIDS, Sao Paulo, Brazil, 6Faculdade de Medicina do ABC and Hospital Heliópolis, Sao Paulo, Brazil, 7University Hospital Basel, Basel, Switzerland, 8Boehringer Ingelheim Pharmaceuticals Inc, Ridgefield, CT, United States, 9Boehringer Ingelheim España, Barcelona, Spain, 10Mount Sinai Medical Center, New York, NY, United States

**Background:** Faldaprevir (FDV) is a potent, once-daily HCV NS3/4A protease inhibitor being developed for the treatment of chronic HCV infection in mono-infected patients and those co-infected with HIV. In healthy subjects, FDV had no clinically relevant effect on the exposure of tenofovir, darunavir, raltegravir, and efavirenz. The objective of this substudy of STARTVerso4 was to assess the effect of FDV on the pharmacokinetics (PK) of atazanavir/ritonavir (ATV/r) in patients co-infected with HIV and chronic HCV genotype (GT) 1.

**Methodology:** In STARTVerso4, HCV/HIV co-infected patients receiving ATV/r-based highly active antiretroviral therapy (HAART) were assigned to receive FDV 120 mg QD + pegylated interferon alfa-2a/ribavirin (PR) for 24 weeks. Since both ATV and FDV are inhibitors of UGT1A1, patients on an ATV/r regimen with baseline bilirubin levels >2.5 x ULN were excluded. PK sampling was performed at baseline (Day -1) before HCV treatments and after 2 weeks of combined treatment. Concentrations of ATV were determined by a validated HPLC-MS/MS assay. Safety was assessed throughout the study.

**Results:** Among 308 patients treated in STARTVerso4, 12 were on ATV/r-based HAART. ATV steady-state PK was comparable with FDV vs. without FDV: geometric mean ratios of 1.00, 1.02, and 1.09, for AUC0-24h, Cmax, and C24h, respectively (Table). In all 12 patients, the C24h was at least 4x higher than the ATV EC50 for wild-type HIV (14 ng/mL). PK parameters for ritonavir were also similar with and without co-administration of FDV (Table).

Compared with the overall FDV 120 mg study arm, patients on an ATV/r regimen showed a comparable AE profile and a similar incidence of bilirubin-associated AEs (8.9% overall; 16.7% with ATV/r [jaundice in 2 patients]). Mean increases in total bilirubin from baseline to week 4 were 0.9 mg/dL for FDV 120 mg overall and 1.1 mg/dL for patients on ATV/r; increases were mainly unconjugated bilirubin (0.7 mg/dL and 1.0 mg/dL, respectively).

**Conclusions:** In patients co-infected with HIV and HCV, the PK parameters of ATV/r in the presence of FDV were similar to ATV/r alone. These results indicate that FDV 120 mg QD and ATV/r can be safely co-administered without dose modification in HIV/HCV co-infected patients.

### No Meaningful PK Interaction Between HCV Protease Inhibitor MK-5172 and Tenofovir or Raltegravir

**Wendy W. Yeh**1, Iain P. Fraser2, Luzelena Caro3, Jennifer Talaty4, Zifang Guo4, Henry Davis5, Stephen P. Youngberg6, Joan R. Buterton1

1Clinical Pharmacology/ Clinical Research, Merck Research Laboratories, Boston, MA, United States, 2Clinical Pharmacology/ Clinical Research, Merck Research Laboratories, Rathway, NJ, United States, 3Clinical Drug Metabolism, Merck Research Laboratories, West Point, PA, United States, 4Statistics, Merck Research Laboratories, Upper Gwynedd, PA, United States, 5Clinical Pharmacology/ Clinical Research, Merck Research Laboratories, Upper Gwynedd, PA, United States, 6Celerion, Lincoln, NE, United States

**Background:** MK-5172 is a potent, once-daily inhibitor of the hepatitis C virus (HCV) NS3/4A protease that is being developed for the treatment of chronic HCV infection in mono- and HCV/human immunodeficiency virus (HIV)-coinfected patients. The present study evaluated the pharmacokinetic interactions and tolerability of MK-5172 coadministered either with tenofovir (TDF, HIV NRTI) or raltegravir (RAL, HIV integrase inhibitor) in healthy subjects.

**Methodology:** This was a 2-part, open-label, multiple-dose study in 24 healthy adult male and female volunteers, ages 19-55 years. Part 1: 12 subjects received oral doses of 300 mg TDF once daily on Days 1 to 7 in Period 1. After an 8 day washout, subjects received oral doses of 200 mg MK-5172...
Effect of Faldaprevir On Raltegravir Pharmacokinetics in Healthy Volunteers

David Joseph\textsuperscript{1}, Peter Rose\textsuperscript{2}, Natalja Streilkowa\textsuperscript{2}, Armin Schultz\textsuperscript{3}, Jeanette Garcia\textsuperscript{1}, Mabrouk Elgadi\textsuperscript{4}, Fenglei Huang\textsuperscript{1}

\textsuperscript{1}Boehringer Ingelheim Pharmaceuticals, Inc, Ridgefield, CT, United States, \textsuperscript{2}Boehringer Ingelheim Pharma GmbH & Co KG, Biberach, Germany, \textsuperscript{3}CRS Clinical Research Services Mannheim GmbH, Mannheim, Germany, \textsuperscript{4}Boehringer Ingelheim (Canada), Ltd, Burlington, ON, Canada

Background: Faldaprevir (FDV) is a potent, once-daily HCV NS3/4A protease inhibitor being developed for the treatment of chronic HCV infection in mono-infected patients and patients co-infected with HIV. Raltegravir (RAL), an HIV integrase inhibitor, might be used in combination with FDV to treat HIV patients co-infected with chronic HCV. The objective of this study was to assess the effect of FDV on the steady state pharmacokinetics of RAL.

Methodology: This was an open-label, 2-period, fixed-sequence study in healthy subjects (N=24; 12 males and 12 females). FDV and RAL were administered as 240 mg and 400 mg doses, respectively. Treatment A: RAL BID on Days 1-3, RAL QD on Day 4; Treatment B: RAL BID and FDV BID (loading dose) on Day 1, RAL BID and FDV QD on Days 2-5 in Period 1. In Period 2, multiple oral doses of RAL did not meaningfully alter the steady-state pharmacokinetics of RAL with (RAL+FDV/RAL) GMRs [90% CIs] of 1.43 [0.89, 2.3], 1.46 [0.78, 2.73], and 1.47 [1.08, 2.00], respectively. Multiple oral doses of RAL did not meaningfully alter the steady-state pharmacokinetics of RAL with (RAL+FDV/RAL) GMRs [90% CIs] of 0.86 [0.65, 1.12], 0.78 [0.51, 1.18], and 0.89 [0.78, 1.01], respectively.

Results: Co-administration of MK-5172 with either TDF or RAL was generally well-tolerated. In Part 1, multiple oral doses of MK-5172 slightly increased the steady-state AUC\textsubscript{0-24h}, C\textsubscript{max}, and C\textsubscript{ss} of TDF with (MK-5172+TDF/MK-5172) geometric mean ratios (GMRs) [90% confidence intervals (CIs)] of 1.18 [1.09, 1.28], 1.14 [1.04, 1.25], and 1.24 [1.10, 1.39], respectively. Multiple oral doses of tenofovir did not meaningfully alter the steady-state AUC\textsubscript{0-24h}, C\textsubscript{max}, or C\textsubscript{ss} of MK-5172 with (MK-5172+TDF/MK-5172) GMRs [90% CIs] of 1.15 [1.07, 1.25], 1.20 [1.11, 1.31], and 1.29 [1.19, 1.40], respectively. In Part 2, multiple oral doses of MK-5172 did not meaningfully alter the steady-state AUC\textsubscript{0-24h}, C\textsubscript{max}, or C\textsubscript{ss} of RAL with (RAL+MK-5172/RAL) GMRs [90% CIs] of 1.43 [0.89, 2.3], 1.46 [0.78, 2.73], and 1.47 [1.08, 2.00], respectively. Multiple oral doses of RAL did not meaningfully alter the steady-state AUC\textsubscript{0-24h}, C\textsubscript{max}, or C\textsubscript{ss} of MK-5172 with (MK-5172+RAL/MK-5172) GMRs [90% CIs] of 0.91 [0.72, 1.15], 0.85 [0.62, 1.16], and 0.90 [0.82, 0.99], respectively.

Conclusions: The coadministration of MK-5172 with TDF, or MK-5172 and RAL in healthy volunteers did not result in clinically significant drug-drug interactions. These results suggest that no dose adjustments of MK-5172, TDF, or RAL are needed for coadministration in HCV/HIV coinfected patients and support further studies of MK-5172 with ARV regimens based on TDF and RAL in the co-infected population.

502 No Clinically Relevant Interactions Between Daclatasvir and Cyclosporine or Tacrolimus

Marc Bifano\textsuperscript{1}, Robert Adamczyk\textsuperscript{2}, Carey Hwang\textsuperscript{3}, Hamza Kandoussi\textsuperscript{4}, Alan Marion\textsuperscript{5}, Richard J. Bertz\textsuperscript{6}

\textsuperscript{1}Research and Development, Bristol-Myers Squibb, Hopewell, NJ, United States, \textsuperscript{2}Research and Development, Bristol-Myers Squibb, Lawrenceville, NJ, United States, \textsuperscript{3}ICON Development Solutions, Omaha, NE, United States

Background: Chronic HCV infection is the main cause of liver transplantation (LT). HCV recurrence, seen in ~50% of HCV-infected LT patients during the first postoperative year, is the main cause of graft failure (despite long-term treatment with immunosuppressants eg cyclosporine [CSP] or tacrolimus...
Daclatasvir (DCV), a first-in-class HCV NS5A inhibitor with pan-genotypic activity in vitro and demonstrated clinical efficacy as part of multiple (including all-oral) regimens, has a pharmacokinetic (PK) profile supportive of QD dosing and a low probability of DDIs as a perpetrator and manageable DDIs as a victim. It is anticipated that DCV will be co-administered with CSP and TAC in the clinical setting.

**Methodology:** Healthy fasted subjects (age 18-49 years; BMI 18-32 kg/m²) received a single oral dose of CSP 400 mg on Days 1 and 9 and DCV 60 mg QD on Days 4-11 (Group 1), or received a single oral dose of CSP 5 mg on Days 1 and 13 and DCV 60 mg QD on Days 8-19 (Group 2). Blood samples for PK analysis were collected on Days 1 and 9 for CSP (72h), 1 and 13 for TAC (168h), and 8 and 9 (Group 1) or 12 and 13 (Group 2) for DCV (24h). Statistical analyses (geometric mean ratios [GMR] and 90% confidence intervals [CI]) on the PK parameters of CSP, TAC and DCV (max. plasma conc. [Cmax], AUC from time zero until the time of last quantifiable concentration [AUC0,τ], end of the dosing interval [AUC0-TAU] or extrapolated to infinity [AUC0-∞] and plasma conc. 24h post-dose [C24]) were performed.

**Results:** Evaluable data from 14 subjects in each group were collected. DCV did not affect the PK parameters of either CSP or TAC, and TAC did not affect the PK parameters of DCV; all GMRs were close to 1 and the 90% CIs were contained within the accepted no-effect boundary (0.80-1.25). Co-administration of CSP resulted in modest increases in DCV AUC0-TAU (40%) and C24 (56%); Cmax was unaffected.

**Conclusions:** No clinically-relevant DDIs were observed when DCV was co-administered with CSP or TAC; CSP caused a modest increase in DCV exposure. Dose adjustments for DCV, TAC, or CSP during co-administration of DCV with CSP or TAC are unlikely to be required.

---

**ABCC4 3348 T>C SNP Affects Tenofovir Urinary Output in HIV-Positive Patients**

Andrea Calcagno, Jessica Cusato, Letizia Marinaro, Marco Simiele, Alice Trentalange, Chiara Montrucchio, Chiara Alcantarini, Antonio D’Avolio, Giovanni Di Perri, Stefano Bonora

Unit of Infectious Diseases, Department of Medical Sciences, University of Torino, Torino, Italy

**Background:** Several proteins have been involved in tenofovir transport both in the intestinal lumen and at the proximal tubular renal cells; single nucleotide polymorphisms (SNPs) in ABCC2 and ABCC10 have been associated with kidney tubular dysfunction along with tenofovir exposure. No study has so far assessed the influence of genetic profile on urinary and plasmatic tenofovir pharmacokinetic parameters.

**Methodology:** Adult HIV-positive patients on tenofovir-containing HAARTs since at least six months, presenting estimated creatinine clearance (eCRCL) above 60 ml/min and signing an informed consent were included. Twelve hours tenofovir plasma (pC₁₂) and urinary concentration (uC₁₂) were measured through HPLC/MS-MS methods. SNPs in the following genes were obtained through real-time PCR: ABCC1, ABCC2, ABCC4, ABCC10, AK1, SLC22A6, hENT1, CNT2. Results are expressed as median (IQR); non-parametric tests were used for all analysis.

**Results:** 194 patients (70.1% male) were enrolled. Age, BMI and eCRCL were 45.2 years (39-51), 23.7 kg/m² (21.8-26.0) and 91.7 ml/min (80-109) respectively. Tenofovir pC₁₂ and uC₁₂ were respectively 68 ng/mL (50-97) and 25722 ng/mL (14437-38598) with a U/P ratio of 398 (230-610). Tenofovir pC₁₂ correlated with age (rho=0.21, p=0.03) and eCRCL (rho=-0.22, p=0.002) while uC₁₂ with BMI (rho=-0.15, p=0.04); U/P ratio correlated with age (rho=-0.17, p=0.02) and borderline with eCRCL (rho=-0.07). Urine-to-plasma tenofovir ratio was lower in ABCC4 3348 (rs1751034) CC carriers [87.5 (50-170) vs. 396 (235-558), p=0.008], in ABCC10 2759 (rs2125739) TT carriers [386 (214-38) vs. 451 (314-743), p=0.028], in ABCC1 3435 (rs1045642) TT carriers [311 (150-444) vs. 406 (238-671), p=0.024], in SLC22A6 (rs11854484) CT/TT carriers [386 (214-505) vs. 438 (247-683), p=0.042]. At multivariate linear regression analysis (including BMI, ethnicity, gender, tenofovir duration, PI use, ABCC1 3435 SNPs, ABCC10 2759 SNPs) age (p=0.001, 95CI 3.2-16.4) and ABCC4 3348 CC genotype (p=0.041, 95CI 14.5-679) were independent predictors of tenofovir urinary output.

**Conclusions:** Age and single nucleotide polymorphisms in the ABCC4 gene are independent predictors of tenofovir urinary output: this finding confirms the relationship between genetic factors and tenofovir exposure in the suggested mechanism underlying proximal tubular dysfunction. Given the interplay between genetic and pharmacokinetic factors in determining renal tubular damage, treatment tailoring in tenofovir-treated patients deserves further clinical evaluation.
504 Relative Genetic Contribution To the Pharmacokinetics of Commonly Prescribed Antiretrovirals

Marco S. Siccardi1, Adeniyi Olagunju1,2, Marco Simiele1, Antonio D’Avolio3, Andrea Calcagno2, Giovanni Di Perri2, Stefano Bonora2, Andrew Owen1
1Department of Molecular and Clinical Pharmacology, University of Liverpool, Liverpool, United Kingdom, 2Faculty of Pharmacy, Obafemi Awolowo University, Ile-Ife, Nigeria, 3Amedeo di Savoia Hospital, University of Turin, Turin, Italy

Background: Variability in antiretroviral pharmacokinetics is influenced by numerous factors affecting absorption, distribution, metabolism and elimination. Recently, a relative genetic contribution (rGC) of 0.904 (0.64 - 0.97) was reported for nevirapine (NVP) AUC0-6h (Micheli et al, Pharmacogenet Genomics, 2013). The aim of this study was to assess the rGC of a panel of antiretroviral drugs to assess the degree by which heritability influences their pharmacokinetics.

Methodology: Patients from the Therapeutic Drug Monitoring Registries of the University of Turin and the University of Liverpool were included in the study. Inclusion criteria were as follows: receiving boosted lopinavir (LPV/r, 300/100 mg b.i.d.), boosted atazanavir (ATV/r 300/100 q.d.), unboosted ATV (ATV, 400mg q.d.), efavirenz (EFV, 600 mg q.d.), NVP (400 mg q.d.) or raltegravir (RAL, 400 mg b.i.d), age>18 years, not receiving drugs known to contribute to drug-drug interactions. Plasma drug concentrations were determined using HPLC or LC-MS/MS methods. Intrapatient (SDw) and interpatient (SDb) variability were measured in patients with Cmin or C12h available from more than one visit. The rGC was calculated using the following equation: 1-(1/F) where F = SDb2/SDw2. Statistical significance for genetic contribution was calculated using F-test, α = 0.05.

Results: A total of 211 patients were included in the study. SDw and SDb were 38% and 43% for LPV/r (n = 37), 49% and 50% for ATV/r (n = 24), 54% and 104% for ATV (n = 24), 33% and 60% for EFV (n = 82), 19% and 44% for NVP (n = 20), and 81% and 95% for RAL (n = 24), respectively. Mean with 95% CI rGC was calculated to be 0.35 (0.06 - 0.55) for LPV/r, 0.15 (0 - 0.6) for ATV/r, 0.55 (0.33 - 0.7) for ATV, 0.78 (0.68 - 0.85) for EFV, 0.82 (0.62 - 0.91) for NVP and 0.08 (0 - 0.56) for RAL (Figure). Genetic contribution was statistically significant (p < 0.05) for ATV, EFV and NVP. All patients were of Caucasian ancestry and neither age nor gender was significantly associated with plasma concentrations for any drug.

Conclusions: The rank order for genetic contribution to variability in PK for the study drugs was NVP > EFV > ATV > LPV/r > ATV/r > RAL indicating class-specific differences exist. Interestingly, these data indicate that ritonavir reduces the genetic contribution to variability in ATV concentrations presumably through inhibition of gene products such as CYP3A4 and ABCB1. Drugs with higher rGC scores may represent better candidates for pharmacogenetic studies.

505 Leveraging Genomics in HIV Treatment Decisions

Paul J. McLaren1, Margalida Rotger1, Manel Aouri1, Huldrych Günthard2, Catica Marzolini1, Laurent Decosterd1, Amalio Telenti1
1The Swiss HIV Cohort, Lausanne, Switzerland, 2The Swiss HIV Cohort, Zurich, Switzerland

Background: Patient genotype influences outcome of HIV infection and treatment. In a pilot project, we test implementation (operational, semantic, procedures for delivery), doctor’s perception and predictive power of a custom genotyping array that synthesizes current knowledge on genetic variants that contribute to clinical phenotypes in HIV.

Methodology: The array includes 4,146 SNPs that capture known functional variants and tags common variation (>5% frequency) in relevant genes and also allows prediction of class I HLA types. Of these, 81 SNPs are reported markers associated with HIV/HCV disease progression, adverse drug events, pharmacokinetics or metabolic traits.

Results: In this first interim analysis, 89 HIV infected patients were enrolled prior to the initiation of cART. Genotyping was performed and reports of genetic predisposition were returned to clinicians after initiation of treatment. Of these, 84 (94%) carried genetic risk factors for at least one trait. To assess predictive power, we explored metabolic parameters and drug levels in detail. A total of 203 metabolite measurements were available for bilirubin, HDL cholesterol, non-HDL cholesterol, triglycerides and glucose and 28 measurements of drug levels for which genetic predictions exist (EFV, ETV and LPV/r). We observed 39 metabolite measurements that exceeded the threshold for reporting. In 5 individuals (13%), relevant genotypes were observed and correct predictions made. Conversely, 13 of 164 individuals (8%) carried relevant genetic markers without the associated trait. We observed 6 drug levels that were either above or below the 75th percentile. In 3 individuals (50%), relevant genotypes were observed and correct predictions made. Conversely, 1 of 22 individuals carried relevant genetic markers without the associated trait. In a survey aimed at gauging the utility of this information as seen by the physician, 57% said they found the information useful or potentially useful. In 7 of 57 (12%) instances, the treating physician would have been inclined to prescribe a different treatment, 9 of 58 (16%) would consider additional laboratory tests and 20 of 58 (34%) would discuss cardiovascular risk factors.

Conclusions: The interim analysis demonstrates the feasibility and general acceptance of returning genetic data to clinicians and the modest predictive power of the genetic testing. Based on physician responses, these tests could have lead to a change in clinical decisions.
506 Contribution of CYP2A6, UGT2B7, and Other Non-CYP2B6 Polymorphisms To Plasma Efavirenz Exposure

David Haas1, Aweewura Kwara2, Danielle M. Richardson1, Paxton Baker1, Ioannis Papageorgiou1, Edward P. Acosta4, Gene D. Morse5, Michael Court1, the AIDS Clinical Trials Group (ACTG)
1Vanderbilt University, Nashville, TN, United States, 2Brown University, Providence, RI, United States, 3Washington State University, Pullman, WA, United States, *University of Alabama at Birmingham, Birmingham, AL, United States, 5State University of New York at Buffalo, Buffalo, NY, United States

**Background:** Two CYP2B6 variants, 516G→T and 983C→T, define high efavirenz (EFV) concentration strata (slow metabolizers). Contributions by CYP2A6, UGT2B7, and other non-CYP2B6 polymorphisms have been reported, but have been inconsistent. We characterized associations between EFV concentrations and genetic variants in 84 AIDS Clinical Trials Group (ACTG) study participants, all with CYP2B6 516/983 slow metabolizer genotypes.

**Methodology:** Several randomized ACTG treatment trials (esp. A5202, A5095/A5097s, and ACTG 384) included EFV-containing arms, and plasma sampling for EFV at multiple study weeks. We included subjects with minimal intraindividual variability between ≥2 EFV determinations at 8-19 hours post-dose. Slow metabolizer CYP2B6 genotypes (CYP2B6 516TT, 516T/983C, and 983CC) were available from previous analyses. Genotyping of UGT2B7 was by sequencing, and 198 additional loci (107 polymorphic) in 40 drug metabolism/transport genes by iPLEX ADME PGx platform. Race/ethnicity was by self-report. Associations with the mean of log10-transformed EFV concentrations were assessed by linear regression.

**Results:** Analyses included Black (56%), White (29%), and Hispanic (15%) subjects. CYP2B6 genotypes were 516TT in 71 subjects, 516T/983C in 12, and 983CC in 1. EFV concentrations were somewhat higher with 983C alleles (P=0.12). In univariate analyses (additive models), CYP2A6 -48T→G (rs28399433) was significantly associated with increased EFV concentrations in all subjects (P=3.8x10E-4, Figure, top); this was consistent in Black and White groups analyzed separately. UGT2B7 735A→G (rs28365062, *1c) and 801T→A (rs7438284, *2) were not associated with EFV concentrations by univariate analysis (p=0.34 and P=0.63), and after controlling for CYP2A6 -48T→G (p=0.34 and P=0.63, respectively). Homozygosity for UGT2B7 735GG (n=3), but not heterozygosity, was associated with higher EFV concentrations (P=0.006, Figure, bottom). With correction for multiple comparisons, no iPLEX ADME PGx variant other than CYP2A6 -48T→G was associated with EFV concentrations, including 22 in CYP2A6 and 3A4/5.

**Conclusions:** In CYP2B6 slow metabolizers, CYP2A6 -48T→G is associated with higher EFV concentrations. An effect of UGT2B7 735A→G on EFV concentrations, if true, is much less. No other significant associations in these or other genes were found. These findings support a contribution of CYP2A6, and possibly UGT2B7 variants to even higher EFV concentrations in CYP2B6 slow metabolizers.

ARV Pharmacokinetics, Drug Interactions, and Pharmacodynamics

507 Rilpivirine With Darunavir/Ritonavir: Pharmacokinetics & Safety in HIV Therapy-Naïve Patients

Akil G. A. Jackson1, Laura J. Else1, Christopher Higgs1, Zeenat Karolia1, Saye Khoo1, David Back1, Andrew Murungi2, Emma Devitt1, Anton Pozniak1, Marta Boffito1
1St Stephen’s AIDS Trust, St Stephen’s Centre, Chelsea & Westminster Hospital, London, United Kingdom, 2Infectious Diseases, Janssen UK, High Wycombe, United Kingdom

**Background:** A combination of ritonavir-boosted darunavir (DRV/rtv) and rilpivirine (RPV) could potentially form a once-daily nucleoside-sparing regime for therapy-naïve treatment. RPV is subject to the boosting effect of hepatic cytochrome inhibition, and in an interaction study in healthy volunteers DRV/rtv increased RPV pharmacokinetic (PK) exposures, of a RPV 150mg daily dose, by 80 to 180% without altering DRV or rtv. This study investigates the safety, steady state PK and antiviral activity of this combination in therapy-naïve HIV-infected adults.

**Methodology:** HIV-1 infected adults, after giving informed consent, were screened by medical history, examination, laboratory bloods and ECG. Important exclusion criteria were: significantly abnormal ECG (particularly QT prolongation), hepatitis B or C co-infection, screening viral genotype showing reduced
sustainability to planned therapy, and use of any drug with PK interaction with study medications. All received treatment with DRV/rtv 800/100mg and RPV 25mg once daily, administered with a meal of > 533kcal, and weekly viral load (VL) monitoring was performed prior to a formal 24hr PK profile at day 28. Ongoing monitoring of clinical response continued to 48 weeks. RPV, DRV and rtv plasma concentrations were determined by validated HPLC-MS/MS method; PK parameters (Cmax, Ctrough and AUC0-24h) were determined using non-compartmental analyses (WinNonLin).

Results: Twenty-five eligible patients were enrolled (majority white males with 1 white female and 4 Hispanic). In ten, viral load at baseline was above 5.0 log10 copies/mL (median 4.7, range 3.0 - 7.7). There was no significant change from baseline in corrected QT interval (Friderecia method), and no clinical or laboratory adverse events of greater than grade2 intensity or of a serious nature were observed. At day 28, geometric mean (90% confidence intervals) of RPV Cmax, Ctrough and AUC0-24h were 183 (171 - 233) ng/mL, 114 (108 - 146) ng/mL and 2966 (2793 - 3731) ng.h/mL; higher on average than RPV PK parameters with NRTI, but within the range observed in phase III patient studies. DRV and rtv exposures were consistent with historical controls. Median VL reduction from baseline, comparing pre-treatment VL below to above 5.0 (log10 copies/mL) respectively, was 2.0 versus 2.1 at day 28 and 2.3 versus 2.5 at day 56.

Conclusions: The combination of DRV/rtv and RPV in this study was well tolerated, giving PK exposures of RPV within the range of those in the ECHO and THRIVE studies. Good initial virologic responses, independent of baseline viral load, and good safety data supports further exploration of this regime for first-line, nucleoside-sparing therapy.

508 Rilpivirine Pharmacokinetics With/Without Darunavir/r in Adolescents and Young Adults
Marc Foca1, Ram Yogev2, Andrew Wiznia3, Rohan Hazra4, Patrick Jean-Philippe5, Bobbie Graham6, Paula Britto7, Vincent J. Carey7, Jennifer King7, Tim R. Cressy8, for the IMPAACT P1058A team

1Pediatrics, Columbia University Medical Center, New York, NY, United States, 2Pediatrics, Lurie Children’s Hospital of Chicago, Northwestern University Feinberg School of Medicine, Chicago, IL, United States, 3Pediatrics, Jacobi Medical Center, Bronx, NY, United States, 4National Institutes of Health, Eunice Kennedy Shriver National Institute of Child Health and Human Development, Maternal and Pediatric Infectious Disease Branch, Bethesda, MD, United States, 5Henry Jackson Foundation, National Institutes of Health, Division of Acquired Immunodeficiency Syndrome, International Maternal Adolescent Pediatric Branch, Bethesda, MD, United States, 6Frontier Science & Technology, Amherst, NY, United States, 7Harvard School of Public Health, Boston, MA, United States, 8The University of Alabama at Birmingham, Birmingham, AL, United States, 9Faculty of Associated Medical Sciences, Chiang Mai University, Chiang Mai, Thailand

Background: Rilpivirine (RPV), a second generation non-nucleoside reverse transcriptase inhibitor (NNRTI), is not recommended for patients <18 years of age. Once daily dosing of RPV makes it an attractive option for HIV-infected adolescents. We report the pharmacokinetic (PK) data of RPV once daily either alone or in combination with DRV/rtv as part of antiretroviral therapy in HIV-infected adolescents and young adults.

Methodology: IMPAACT P1058A is an ongoing observational study designed to evaluate the PK of antiretroviral drug combinations commonly used by HIV-infected children and adolescents. Patients <24 years old receiving RPV 25 mg once daily (with background NRTIs) either alone or combined with DRV/rtv 800/100 mg once daily were enrolled. Plasma samples were collected at pre-dose and 1, 2, 4, 6, 8, 12 and 24 hours after an observed dose. RPV and DRV plasma concentrations were determined using validated HPLC-UV and LC-MS/MS assays, respectively. The 90% confidence intervals (90% CI) for the geometric mean (GM) of the AUC and Cmin were compared with target ranges reported in adults.

Results: Data from 26 subjects were analyzed; 15 receiving RPV alone (8 male), and 11 receiving RPV in combination with DRV/rtv (7 males). The median (range) age and weight were 20 (13-23) years and 75 (40-117) kg, in the RPV alone group, and 20 (17-23) years and 68 (49-97) kg in the combination group. RPV and DRV PK parameters and adult target ranges are presented below:

The mean RPV AUC and Cmin for RPV alone were within the adult target ranges and the 90% CI had substantial overlap. In contrast, the mean and entire 90% CI for AUC and Cmin for RPV substantially exceeded the corresponding adult target when co-administered with DRV/rtv.

Conclusions: RPV alone in this age group provides similar exposure to adults. However, RPV exposure in patients receiving concomitant DRV/rtv was elevated two to three fold. It remains to be determined if this increased exposure leads to increased toxicity or side effect profiles, but currently, RPV dose reduction is not recommended. Further studies of this interaction are warranted.

The Cerebrospinal Fluid HIV Risk Score for Assessing Central Nervous System HIV Activity
Edward R. Hammond1, Rosa M. Crum1, Glenn J. Teitsma1, Shruti H. Mehta1, David B. Clifford2, David M. Simpson3, Benjamin B. Gelman4, Ronald J. Ellis5, Scott L. Letendre6, Justin C. McArthur
1Johns Hopkins University, Baltimore, MD, United States, 2Washington University, St. Louis, MO, United States, 3Icahn School of Medicine at Mount Sinai, New York, NY, United States, 4University of Texas, Medical Branch, Galveston, TX, United States, 5University of California, San Diego, CA, United States

Background: Detectable cerebrospinal (CSF) HIV ribonucleic acid (RNA) is associated with central nervous system (CNS) complications, including neurocognitive impairment and depression. Routine monitoring of CSF HIV RNA presents a valuable key to reducing HIV CNS complications. However, lumbar puncture procedures pose resource utilization challenges. We developed a prediction model to estimate the risk of detectable CSF HIV RNA (threshold >50 copies/ml) that will help identify patients who might benefit most from CSF monitoring.

Methodology: The CNS HIV Anti-Retroviral Therapy Effects Research (CHARTER) prospective cohort is an ongoing 6-Center, US-based study. We evaluated 811 participants on combination antiretroviral therapy (cART) who underwent CSF evaluation at study entry (2004-2007). We applied points to the final multivariable logistic regression prediction model to develop a detectable CSF HIV Risk Score.

Results: Plasma HIV RNA, CNS Penetration Effectiveness (CPE 2.0), duration of cART, adherence, race and depression were retained predictors of CSF HIV RNA (Table 1). The CSF HIV Risk Score ranges from 0 to 42 points and displays good calibration, Hosmer-Lemeshow P-value=0.85, and discrimination, c-statistic=0.90. The distribution of risk scores in our sample ranged from 0 to 39 points, with mean [standard deviation (SD)] of 15.4 (7.3). Predicted probabilities [95% Confidence Interval (CI)] for detectable CSF HIV RNA at various CSF HIV Risk Scores include; 10 = 2.3% (95% CI: 1.5-3.7); 15 = 7.0% (95% CI: 5.1-9.5); 20 = 19.2% (95% CI: 15.7-23.2); 25 = 42.9% (95% CI: 34.6-49.6); and 30 = 70.3% (95% CI: 61.5-77.9). For example, a Black patient (3 points), with plasma HIV RNA of 300 copies/ml (10 points), who is presently depressed (4 points), and is fully adherent to cART regimen (0 points), with total CPE score of 9 (6 points), for a duration of 10 months (4 points; total CSF HIV Risk Score = 27 points), has a 54.3% (95% CI: 46.5-62.0) probability of detecting CSF HIV RNA. For each point increase, the odds of detecting CSF HIV RNA increase by 26% (Odds Ratio = 1.26, 95% CI 1.21-1.31; P<0.01).

Conclusions: The CSF HIV Risk Score predicts detection of HIV RNA in the CSF. An elevated risk score suggests which patients will benefit from CSF monitoring. It presents an advance in HIV management and monitoring of CNS effects of HIV, and provides a potentially useful tool for clinicians.

Efavirenz (EFV) 400 Versus 600 mg Daily: Results of the ENCORE1 Intensive PK Substudy
Laura Dickinson1, Rebekah Puls2, on behalf of ENCORE1 Pharmacokinetics Substudy Group
1Department of Molecular and Clinical Pharmacology, University of Liverpool, Liverpool, United Kingdom, 2University of New South Wales, Sydney, Australia

Background: ENCORE1 is an ongoing study in treatment-naïve, HIV-1 infected adults randomized to TDF/FTC with either reduced (400 mg, EFV400) or standard dose EFV (600 mg, EFV600). EFV400 was virologically non-inferior to EFV600 with greater than 80% suppression to <50 HIV-RNA copies/ml in both groups at 48 weeks. This intensive pharmacokinetic (PK) study compared EFV plasma exposures between doses in a subset of subjects.

Methodology: Serial 24 hour plasma samples were collected between weeks 4 and 8 from subjects consenting prior to randomization in the parent trial. EFV concentrations were determined by validated LC-MS/MS and steady-state PK parameters calculated using WinNonlin™. To assess between-dose differences in parameters, geometric mean ratios (GMR) and 90% CI were calculated using log transformed data, then expressed as linear values (primary analysis). Given that log transformation did not correct for non-normality of data, post-hoc non-parametric analysis was performed (Mann-Whitney U test).
### Results

Forty-six (15 female) subjects were enrolled at four study sites: Argentina, South Africa, Thailand, and the United Kingdom. Despite disparate numbers in treatment groups (EFV400 = 28, EFV600 = 18), substudy arms were matched for age (mean 36 yrs), BMI (mean 25 kg/m²) and ethnicity [17 (37%) African, 10 (22%) Asian, and 19 (41%) Caucasian]. PK parameters are summarised (Table 1). EFV AUC0–24, Cmax, and C12 (representing mid-dose interval concentration) were significantly lower for EFV400. C12 was <1.0 mg/L (suggested MEC) in 7 (25%) EFV400 and 1 (6%) EFV600 participants, and the C24 <1.0 mg/L in 13 (46%) EFV400 and 5 (28%) EFV600 subjects, respectively. Three subjects did not complete week 48 (EFV400 = 2, EFV600 = 1). At week 48 for EFV400, 3 (11%) had HIV-RNA >50 copies/mL, 2 of which had C12 and C24 <MEC at the time of sampling. For EFV600, 4 (22%) patients had >50 copies/mL, 1 of which had C12 below 1.0 mg/L.

### Conclusions

Dose-proportional plasma exposure to EFV was observed. Subjects receiving EFV400 had comparable virological suppression consistent with the main ENCORE1 study) at week 48 despite lower AUC0–24 and C12 and a higher proportion of subjects below the recommended MEC at PK sampling (week 4–8). This suggests that C12 or C24 lower than 1.0 mg/L was not associated with virus suppression at 48 weeks in this population. Taken together with the ENCORE1 results, these results challenge the conventional PK targets for therapeutic success.

### Correlation Between Atazanavir Concentrations, Clinical Covariates and Side Effects

**Cristina J. P. Gervasoni, Paola Meraviglia, Simona Landonio, Valeria Cozzi, Agostino Riva, Nitin Charbe, Laurenzia Ferraris, Giuliano Rizzardini, Massimo Galli, Dario Cattaneo**

Luigi Sacco University Hospital, Milan, Italy

**Background:** Although significant relationships have been reported between atazanavir (ATV) trough concentrations and clinical outcome, therapeutic drug monitoring (TDM) of ATV is not routinely adopted in clinical practice. ATV plasma concentrations >150 ng/mL are currently considered the minimum level needed to achieve viral undetectability, while concentrations >800 ng/mL are associated with increased risk of hyperbilirubinemia. No specific associations have been reported between ATV levels and other drug-related complications. Similarly, no clinical covariates affecting ATV concentrations have been conclusively identified.

**Methodology:** ATV trough concentrations were determined in a consecutive series of HIV patients receiving ATV for at least 3 months. The presence of hyperbilirubinemia (total bilirubin >1.8 mg/dL excluding UGT1A1*28 homozygous genotype), dyslipidemia (total cholesterol >200 mg/dL, triglycerides >180 mg/dL or statin therapy) and nephrolithiasis (renal colics without urinary oxalate or urate crystals) were assessed. Multivariate regression analyses were performed using ATV-related complications as the dependent variable and demographic, clinical and laboratory data as independent covariates.

**Results:** Nearly 45% of 273 enrolled patients (68% on ATV/r 300/100) had ATV concentrations out of the therapeutic drug window (set at 150–800 ng/mL). Patients with hyperbilirubinemia (n=125), hypercholesterolemia (n=116), hypertriglyceridemia (n=92) or nephrolithiasis (n=13) had ATV concentrations significantly higher (1025±920, 770±858, 838±791 or 1121±886 ng/mL, respectively) compared with those measured in patients without ATV-related complications (n=71; 461±678 ng/mL, p<0.001). The independent significant association between ATV plasma concentrations and drug-related toxicity was confirmed also by multivariate logistic regression analysis (p<0.05). The only factors independently associated with ATV levels were ritonavir use (r=-0.291, p<0.0001) and concomitant statin administration (rosuvastatin in 31/34 cases; r= 0.315, p<0.0001). No effect of tenofovir, patients’ age, body weight or body mass index on ATV concentrations was found.

**Conclusions:** A significant proportion of patients treated with ATV had plasma concentrations exceeding the upper therapeutic threshold. High ATV plasma levels were significantly associated with all the main ATV-related toxicities. TDM in the day-by-day clinical practice may allow an early identification of patients at risk for untoward effects and drug dosage adjustment. Despite rosuvastatin is considered to have a low potential for drug-to-drug interactions with protease inhibitors, our data show that ATV plasma concentrations were significantly influenced by this drug.

Tenofovir Diphosphate Concentration-Response Relationship for HIV Prevention in Vaginal Tissue
Melanie R. Nicoll, Cindi W. Emerson, Julie A. Nelson, Craig Sykes, Heather MA Prince, Kristine B. Patterson, Angela D. M. Kashuba
1School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 2Center for AIDS Research, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 3Microbiology and Immunology, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 4Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Background: Clinical trials with daily dosing of tenofovir (TFV) + emtricitabine have shown disparate results for HIV protection. It is still unknown what target tissue concentrations must be achieved to confer protection. Here we describe the utility of a novel ex vivo human mucosal tissue culture model to determine the tenofovir diphosphate (TFVDP) target for protection.

Methodology: Fresh vaginal tissue was collected from 8 women undergoing surgical repair for vaginal prolapse. 5 subjects were used to characterize TFVDP formation and elimination over 96h. 3 subjects were used for HIV challenge, whereby to 35 3mm punch biopsies (Miltex) per donor were incubated in a range of TFV concentrations (0, 0.1, 1, 10, 100 ug/mL) for 24h. TFVDP was quantified using a validated LC-MS/MS method. Remaining explants were incubated for 3h with 10^7 TCID50 HIV-1JR-CSF, rinsed, and transferred to gelfoam rafts. Explants were harvested every 24h from 0-72h post-infection, with total RNA extracted using RNeasy Kit (Qiagen) and first strand cDNA synthesis performed with Superscript Vilo cDNA Synthesis Kit (Invitrogen). A quantitative RT-PCR assay measured copies of a spliced RNA variant expressed in abundance early in the transcription life cycle, and normalized for tissue weight. Infection was quantified as AUC24-72h adjusted for baseline. EC50 estimates were generated using an Emax model (Sigma Plot) and compared to estimates obtained in the TZM-bl cell line using a luciferase reporter assay.

Results: Vaginal explants phosphorylated TFV to TFVDP at a median molar conversion rate of 0.2% (range 0-20 %) and reached maximal conversion at 24h. TFVDP elimination half-life was 20h. Viral infection was confirmed by a peak in spliced RNA >1.5-fold baseline, and peaked at 2 days after infection. There was a poor relationship between TFV concentration and HIV protection. When normalized for TFVDP, standard error of the estimated EC50 was reduced by 4 logs. Estimated EC50 of TFVDP was 909 fmol/mg in explant tissue and 20 fmol/mg in TZM-bl cells.

Conclusions: This method uses an RS, T-cell-tropic virus to mimic the virus implicated in mucosal HIV transmission. When coupled with a novel spliced RNA assay, an Emax model of TFVDP was generated using 72h incubations. Variable phosphorylation resulted in a more reliable EC50 estimate when TFVDP (the active intracellular moiety) was used, rather than TFV incubation concentrations. Likely representing a “worst case scenario”, this EC50 was ~45 times higher than a standard cellular model, but consistent with other recent clinical data. We are currently using this model to test additional drugs and drug combinations to identify target mucosal concentrations for protection against HIV infection, and determine its utility in PrEP development.

513  
A Pharmacokinetic Drug-Drug Interaction Study Between Raltegravir and Atorvastatin
Maren Blonk, Michiel van Beek, Angela Colbers, Monique Roukens, Bas Schouwenberg, David Burger
1Department of Pharmacy, Radboud University Medical Center, Nijmegen, Netherlands, 2Department of Pharmacology and Toxicology, Radboud University Medical Center, Nijmegen, Netherlands

Background: Dyslipidemia is highly prevalent among patients with HIV infection and contributes to an increased risk of cardiovascular disease. Atorvastatin is a potent lipid-lowering agent and is used for prevention of cardiovascular disease. A complicating factor in the concomitant use of antiretroviral agents and statins is the occurrence of drug-drug interactions. This study was designed to investigate the influence of a frequently used statin, atorvastatin, on the pharmacokinetics of the HIV integrase inhibitor raltegravir and vice versa.

Methodology: This was an open-label, cross-over, three-period phase I trial in 24 healthy volunteers. Subjects took raltegravir 400 mg BID for 7 days, atorvastatin 20 mg QD for 7 days, and the combination of atorvastatin 20 mg QD + raltegravir 400 mg BID for 7 days with 2-week washout periods in between. Treatment sequence was allocated at random. Intensive steady-state 12- and 24-hour pharmacokinetic (PK) blood sampling was performed on day 7 of each treatment period. PK parameters (AUCtau, Cmax, Cmin) were determined by non-compartmental analysis for raltegravir and the sum of atorvastatin and its active metabolites (atorvastatin-equivalents). Geometric mean ratios (GMR) of the test treatment [combination raltegravir + atorvastatin] versus the reference treatment [raltegravir or atorvastatin alone] and 90% confidence intervals (CI) were calculated after log-transformation of within-subject ratios. Fasting lipid profiles were obtained on day 1 and day 7 of each treatment period to assess short-term effect on serum low-density lipoprotein (LDL) cholesterol. To compare the change in LDL cholesterol after atorvastatin with and without raltegravir a paired t-test was performed.

Results: Twenty-four healthy volunteers, of which 11 males, were enrolled (23 Caucasian, 1 mixed race). One subject did not complete the treatment period with raltegravir alone due to reasons not related to the study. Median (range) age and BMI were 31 (18-55) years and 20.9 (18.3-28.9) kg/m² respectively. No serious adverse events were reported. GMR (90% CI) of raltegravir PK parameters were: 1.01 (0.68-1.51) for AUCtau, 1.14 (0.70-1.86) for Cmax, 0.96 (0.69-1.32) for Cmin, GM (90% CI) of atorvastatin-equivalents PK parameters were: 0.98 (0.91-1.06) for AUCtau, 1.02 (0.83-1.26) for Cmax, 0.97 (0.87-1.10) for Cmin. Mean (95% CI) change in LDL cholesterol (day7 - day1) was -1.12 (-1.37,-0.87) mmol/L for atorvastatin alone compared to -1.29 (-1.50,-1.08) mmol/L for atorvastatin when combined with raltegravir (p=0.19).

Conclusions: Coadministration of raltegravir and atorvastatin does not change the pharmacokinetics of either drug in a clinically meaningful way. The combination can be safely administered without dose adjustments.
**514LB  PK Study of Depot Medroxyprogesterone Acetate in HIV+ Women On Lopinavir/Ritonavir: ACTG 5283**

Susan E. Cohn1, Amneris E. Luque2, Jeong-Gun Park3, Yoninah Cramer4, Francesca Aiweka4, Adriana Weinberg5, Elizabeth Livingston4, Karin L. Klingman6, Barbara Bastow7, Heather Watts3

1Medicine, Northwestern University, Chicago, IL, United States, 2Medicine, University of Rochester Medical Center, Rochester, NY, United States, 3Bristol-Myers Squibb, Jersey City, NJ, United States, 4Biostatistics, Statistical and Data Analysis Center, Boston, MA, United States, 5Biostatistics, University of Rochester Medical Center, Rochester, NY, United States, 6Clinical Pharmacy, University of California San Francisco, San Francisco, CA, United States, 7Medicine, University of Colorado Health Sciences Center, Denver, CO, United States, 8Pediatrics, Duke University, Durham, NC, United States, 9AIDS, Division of AIDS, Bethesda, MD, United States, 10Social and Scientific Systems, Inc., Silver Spring, MD, United States, 11Maternal and Pediatric Infectious Disease Branch, National Institute of Child Health and Human Development, Bethesda, MD, United States

**Background:** Little is known about use of depot medroxyprogesterone acetate (MPA) with boosted-protease inhibitors (PIs), a commonly used antiretroviral treatment regimen. Interactions with boosted PIs could lead to changes in efficacy or toxicity of any of these drugs.

**Methodology:** We prospectively determined the effect of twice daily lopinavir (LPV) 400mg/ritonavir (RTV) 100 mg along with 2 or more nucleoside reverse transcriptase inhibitors (NRTIs) on the PK exposure of MPA through every 2 week sampling from baseline (day 0) to week 12 (AUC 0 to 12wk) (Wilcoxon rank-sum test). We also determined the effect of MPA on the PK of LPV and RTV using AUC for LPV and RTV at baseline and after 4 weeks of depot MPA using intensive PK sampling at pre-dose and 0.5, 1, 2, 3, 4, 5, 6, 8, and 10 hours post-LPV/r dosing (Wilcoxon signed-rank test). Safety and toxicity of depot MPA and ovulation suppression (using progesterone levels of <5ng/mL) were assessed biweekly during the 12-week study, and were compared with 14 HIV+ control subjects not on HIV meds or only NRTIs, previously enrolled in A5093, who received depot MPA with identical assessments. All MPA assays were performed by PPD, Inc.

**Results:** 24 evaluable women on LVP/RTV were enrolled; 58% were black, 25% Hispanic and 13% white; median age 32 years; median CD4 622 cells/mm3; all had HIV RNA<400 copies/mL and negative pregnancy tests. Of the 14 historical controls, 79% were black, 14% Hispanic, and 7% white; median age 33 years. No women appeared to ovulate during the study and there were no pregnancies. MPA concentrations (median AUC0-12wk 18.08 ng/week/mL) were higher than the 14 A5093 controls (median AUC0-12wk 12.38 ng/week/mL) (p<0.001). There were no changes in the LPV/RTV levels after depot MPA (see table below). In this study, possible treatment-related toxicities occurred in 8 (33%) subjects, the most frequent being vaginal bleeding (6), and irritability (2). These side effects are similar to those described with use of DMPA (http://www.accessdata.fda.gov/drugsatfda_docs/label/2010/020246s036lbl.pdf).

**Conclusions:** MPA levels were significantly higher in HIV-infected women taking ritonavir-boosted lopinavir compared to HIV-infected women on no HIV medications or NRTIs alone. Levels of LPV and RTV were not altered by depot MPA and there was no evidence of ovulation through week 12. Depot MPA was well-tolerated despite having AUC levels 46% higher compared to historical controls, and side effects were similar to those reported in women on depot MPA.

**515 Multi-System Investigation of the Mechanisms for Raltegravir Association With Intestinal Tissue**

Darren Michael Moss1, Paul Curley2, Alison Stone3, Marco Siccardi4, Andrew Owen5

1Molecular and Clinical Pharmacology, Translational Medicine, Liverpool, United Kingdom, 2Parasitology, Liverpool School of Tropical Medicine, Liverpool, United Kingdom

**Background:** Recent data have suggested that concentrations of raltegravir (RAL) in gut tissue are high after oral administration to humans, with implications for treatment and prevention. We have used in silico, in vitro, ex vivo and in vivo models to further investigate the accumulation of RAL in gut tissue.

**Methodology:** Gut-to-plasma affinity was predicted in silico for RAL and lopinavir (LPV) using the Poulin Theil equation. Cellular accumulation of RAL and LPV (both 1 µM) was determined at pH 5, 6, 7 and 8 in Caco-2 gut epithelial cells (15x106 cells, 37°C, 30 min). Gut-associated concentrations were determined ex vivo after incubation of 100g rat small intestine (SI) or large intestine (LI) with human plasma (3 mL, 37°C, 4 hours) containing RAL and LPV (both 50 µM). Finally, RAL concentrations in plasma, gut contents, SI and LI were determined after oral dosing (8 mg/kg) to Wistar rats with 1 and 4 hour post-dose blood/tissue sampling. In vivo samples were analysed using LC-MS/MS and other samples were analysed using scintillation counting (3H RAL and 3H LPV).

**Figure 1. Concentrations of RAL in rat plasma, gut and gut contents at 1hr and 4hr post-dose**
Results: Gut-to-plasma affinity ratios for RAL and LPV were predicted to be 0.53 and 6.38 in silico, respectively. Intracellular RAL in Caco-2 cells ranged from 1.41 μM (pH 5) to 0.42 μM (pH 8) and LPV ranged from 24.8 μM (pH 5) to 27.5 μM (pH 8). In ex vivo studies, RAL accumulated less than LPV in both SI (29.6 versus 65.7 μM, p < 0.05) and LI (34.9 versus 53.5 μM, p < 0.05). After oral administration to rats, RAL concentrations decreased in plasma between 1hr (0.63 ± 0.13 μM) and 4hr post-dose (0.05 ± 0.03 μM, p < 0.05) and in SI (1.4 ± 0.26 μM to 0.47 ± 0.27 μM, p < 0.05) but did not change in SI contents (5.2 ± 3.8 μM to 4.0 ± 3.2 μM, p = 0.72). Conversely, increases in LI (0.38 ± 0.15 μM to 1.36 ± 0.50 μM, p < 0.05) and LI contents (0.15 ± 0.09 μM to 40.6 ± 3.3 μM, p < 0.05) were observed (Figure).

Conclusions: RAL accumulated highly in gut tissue in vivo but this was not observed ex vivo or in vitro, indicating that high tissue-associated RAL concentrations in vivo were not driven by plasma-to-tissue accumulation but by high RAL concentrations in gut contents. However, given that intracellular penetration is a prerequisite for RAL activity, further study is required to preclude artefacts that may arise from contamination with gut contents. The gut is a relevant site for both pre-exposure prophylaxis (PrEP) and HIV eradication, and this screening system can be used to select for drugs with preferential accumulation in gut tissue.

516 Tenofovir DF 150 mg Once Daily in HIV-Infected Adults With Moderate Renal Impairment

Tim R. Cressy1, 2, Anchalee Aveling-sanon1, 2, Guttiya Halue2, Pratanna Leenasirimakul4, Nicole Ngo-Giang-Huong1, 2, Achara Eksaengsi5, 6, Gonzague Jourdain1, 7, Virat Klinbuayam5, Churseratana Bowonwanawong1, 2

1Faculty of Associated Medical Sciences, PPHT/IRD 174, Chaing Mai University, Chiang Mai, Thailand, 2Department of Immunology & Infectious Diseases, Harvard School of Public Health, Boston, MA, United States, 3HIV Netherlands Australia Thailand (HIV-NAT) Research Collaboration, Bangkok, Thailand, 4Division of Allergy and Immunology, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, 5PhayaO Hospital, PhayaO, Thailand, 6Nakomping Hospital, Chiang Mai, Thailand, 7Institut de Recherche pour le Development (IRD), Marseille, France, 8The Government Pharmaceutical Organization, Bangkok, Thailand, 9Sanpatong Hospital, Sanpatong, Thailand, 10Internal Medicine, Hospital, Chonburi, Thailand

Background: Renal impairment significantly alters tenofovir pharmacokinetics. The recommended tenofovir disoproxil fumarate (TDF) dose is 300 mg every 48 hours for adults with moderate renal function impairment (creatinine clearance 30-49 ml/min). New dosage strengths and formulations of TDF may permit once daily dosing for these patients. We compared the pharmacokinetics of TDF 300 mg every 48 hours with 150 mg once daily in HIV-infected adults with moderate renal function impairment receiving lopinavir/ritonavir (LPV/r)-based antiretroviral therapy.

Methodology: Phase I, non-randomized, open-label pharmacokinetic study (ClinicalTrials.gov Identifier: NCT01671982). Consenting HIV-positive adults with a confirmed creatinine clearance 30 to <50 ml/min receiving TDF 300 mg every 48 hours as part of LPV/r-based HAART and an HIV-1 RNA viral load (VL) <50 copies/mL were enrolled. HBs-antigen positive adults were excluded. Intensive steady-state 48-hour blood sampling for PK assessment was performed at enrolment; blood samples were collected (pre-dose) and then at 0.5, 1.0, 1.5, 2.0, 4.0, 6.0, 8.0, 12, 24, 36, 48 hours post-dose. Immediately afterwards, the tenofovir dose was changed to 150 mg once daily. Intensive 24-hour blood sampling was repeated 2 weeks later; blood samples were drawn pre-dose, and at 0.5, 1.0, 1.5, 2.0, 4.0, 6.0, 8.0, 12, 24 hours post-dose. Subjects returned to the standard TDF dose after the PK sampling. Tenofovir plasma concentrations were determined using a HPLC assay and tenofovir pharmacokinetic parameters were calculated using noncompartmental analysis.

Results: Twenty HIV-infected adults (40% female) were enrolled. Median (range) age was 53 years (39-82), weight 49.5 kg (37.8-75.1), serum creatinine (SCr) 1.3 mg/dL (0.9-2.1), creatinine clearance (CrCL) 42.0 ml/min (31.7-49.7) and CD4 count 596 cell/mm3 (113-1063). Eighteen subjects had evaluable PK data available. With TDF 300 mg every 48 hours, the TDF AUC0-48h, Cmax and C48h were 9.61 (6.06-18.92) μg.hr/mL, 0.68 (0.44-1.31) μg/L and 0.07 (0.03-0.11), respectively. With TDF 150 mg every 24 hours, the TDF AUC0-24h, Cmax and C24h were 4.80 (2.61-9.29) μg.hr/mL, 0.42 (0.24-0.73) μg/L and 0.10 (0.05-0.20), respectively. The TDF geometric mean ratio (GMR) of AUC0-48h for every 24- versus every 48 hours dosing was 1.00 (90% CI 0.92-1.09). Tenofovir Cmax was significant lower (p<0.01) and Clast (i.e. C48h vs. C24h) significantly higher (p<0.01) with daily TDF dosing. All subjects remained virologically suppressed and no drug-related adverse events were reported.

Conclusions: Switching TDF 300 mg every 48 hours to 150 mg every 24 hours provided equivalent tenofovir exposure in patients with moderate renal function impairment receiving LPV/r-based antiretroviral therapy.
Results: 33/34 control animals acquired SHIV infection, 18 (55%) within the first two weekly inoculations. Five of 6 animals in the -3-day group acquired SHIV, 4 (80%) after the second inoculation, and 1/6 animals in the -3-day/+2h group was infected at the 4th inoculation. No TFV-DP concentrations were below the limit of quantification. Each 5 fmol/10^6 cells of TFV-DP was associated with a 40% reduction in risk of SHIV acquisition (17% to 56%), p = 0.002. The concentration associated with 90% reduction in SHIV acquisition risk (EC90) was 22.6 fmol/10^6 cells, 95% CI (13.8 to 60.8).

Conclusions: This study identified a TFV-DP EC90 of 22.6 (13.8 to 60.8) fmol/10^6 cells for reducing SHIV acquisition risk in a macaque rectal exposure model, which compared well with the TFV-DP EC90 of 16 (3 to 28) fmol/10^6 cells identified in MSM from the iPrEx study. This finding supports the use of this NHP model for PrEP studies using rectal virus challenges and oral TDF/FTC dosing.

New Clinical and Preclinical Formulations

518 Optimisation of Intramuscular Sustained Release Nano-Formulations Using In Silico Modelling
Rajith Kumar Reddy Rajoli¹, David Back¹, Steve Rannard², Andrew Owen¹, Marco Siccardi¹
¹Department of Clinical & Molecular Pharmacology, University of Liverpool, Liverpool, United Kingdom, ²Department of Chemistry, University of Liverpool, Liverpool, United Kingdom

Background: Intramuscular (IM) sustained release antiretroviral (ARV) nano-formulations (NFs) may provide pharmacological options to simplify regimens, reduce drug costs and improve adherence. Studies are currently on-going with injectable preparations for pre-exposure prophylaxis and treatment. The aim of this study was to simulate the pharmacokinetics (PK) of IM sustained release NFs using physiologically based pharmacokinetic (PBPK) modelling. Existing ARVs were assessed for compatibility and theoretical target dose and release rate for once weekly and/or monthly administration formats were identified.

Methodology: In vitro or population PK data for 8 ARVs were integrated into PBPK models and ARV PK was simulated for 100 individuals using MATLAB, R2013b. The models included mathematical descriptions of covariance between demographics and tissue size, expression of metabolic enzymes and processes regulating absorption, distribution and elimination, which are drug-specific. The models were validated against clinical data for oral administration at standard regimens but rilpivirine (RPV) was also validated against available PK data for the 600 mg IM depot. Validated PBPK models were used for the prediction of PK following IM administration of theoretical sustained release NFs. ARV dose and release rate were optimised to obtain Ctrough values above the protein binding corrected IC95 (PBIC95) or clinical cut-offs obtained from literature sources.

* Note that this dose does not apply to the existing RPV formulation. Rather, as for other listed drugs, the data represent a prediction for optimal performance of a reformulation.
Results: The simulated PK parameters for oral administration were in agreement with previously published clinical data. For validation against the existing formulation, simulated 600 mg IM RPV, mean values for AUC were 87.7 vs. 84.0 ng h/mL, Cmax 91.7 vs. 96.7 ng/mL and Ctong 13.3 vs. 15.7 ng/mL for simulated versus observed data with a predicted release rate of 0.0011 /h for the existing formulation. The table gives simulated PK for IM administration and a prediction of the optimal ARV dose and release rate combination. Dolutegravir, efavirenz, emtricitabine, raltegravir, tenofovir and RPV were predicted to be the suitable candidates for monthly IM formats.

Conclusions: PBPK models were used to estimate optimal dose and release rate and may be useful to inform target product profiles for sustained release NPs. Candidates with the potential for reformulation into an IM injection were identified, providing the technological complexities associated with reformulation can be overcome for these agents.

519 Macrophage Targeted Nanomedicines for Mycobacterial Infections
Benson Edagwa1, Dongwei Guo1, Pavan Puligjaa1, JoEllyn McMillian1, Xinming Liu1, Howard Gendelman1, Prabagaran Narayanasmuy1
1University of Nebraska Medical Center, Omaha, NE, United States, 2Pharmaceutical Science, University of Nebraska Medical Center, Omaha, NE, United States

Background: Mycobacterium tuberculosis (MTB) is a common co-morbid HIV-associated infection. Complex drug regimens and microbial resistance underlie an alarming increase of infected people that now exceeds three million worldwide. The needs for access to simplified treatment regimens are of immediate need. This can be achieved by the development of long-acting cell and tissue targeted nanoformulated MTB medicines.

Methodology: Commercially available isoniazid was derivatized to INHP. INHP and rifampin (RIF) poly-lactide-coglycolic acid (PLGA) nanoparticles were manufactured. Physical, chemical properties, cell uptake, retention, viability, trafficking and antimicrobial efficacy were determined for the nanoparticles encapsulated drugs when compared to native drugs. Antimicrobial activities were determined in dose response tests against Mycobacterium smegmatis from one to 15 days after infection.

Results: Results: The nanoformulations displayed enhanced uptake of 4.12 μg/million cells in comparison to 0.1 μg/million cells for the native drugs (Fig. 1A). There was sustained release of the encapsulated drugs that were detectable in monocyte-derived macrophages (MDM) over 15 days; the native drugs were released within 24h (Fig. 1B). Antimicrobial activity was significantly improved up to 10-fold when the two nanoformulations were combined as opposed to native drugs (Fig. 1C). Individual drugs of both nanoformulations and native drugs showed minimum or no antimicrobial effect. We also demonstrated that the nanoformulations and M. smegmatis are trafficked into the same subcellular compartments, thereby enhancing the antimicrobial effect. These trafficking mechanisms parallel what we observed with antiretroviral drugs.

Figure 1: A comparison of drug uptake (A), retention (B) and antimicrobial efficacy study (C) between the nanoformulations (NP) and native drugs (ND)

Conclusions: In summary, we demonstrated that PLGA nanoparticles encapsulating RIF and modified isoniazid derivative improves drug uptake, retention and antimicrobial efficacy of the nanoformulations in comparison to the native drugs. Subcellular distribution study of M. smegmatis and the PLGA nanofomulations show that the drugs and the mycobacterium are trafficked into the same endocytic compartments, thereby enhancing the antimicrobial effect. It should therefore be noted that macrophage-nanoparticle delivery approach is a promising system for the management of tuberculosis in future.

520 Fluorescent Magnetic Nanoparticle as Anti-HIV Drug Carrier for Rodent Brain Targeting
Upal Roy1, Hong Ding1, Sudheesh P. Kanthikeel1, Elena M. Kftanovskaya2, Andrea Raymond1, Karla Munoz-Camaano1, Madhavan Nair1
1Immunology, Florida International University, Miami, FL, United States, 2Department of Human and Molecular Genetics, Florida International University, Miami, FL, United States

Background: HIV-1 still remains one of the leading life-threatening diseases in the world despite the introduction of Highly Active Antiretroviral Therapy (HAART). Since most of the drugs have less penetrance into viral reservoir sites such as brain, development of an active targeted drug delivery system is essential to increase the efficacy of drug targeting to the brain. In this regard, we developed a multifunctional iron oxide magnetic nanoparticle (MNP) bound to anti-HIV drug azidothymidine 5′-triphosphate (AZTTP) (MNP-AZTTP) tagged with fluorescent probe for noninvasive imaging in our lab for targeting to brain. Our initial observation on in vitro study indicated that MNP-AZTTP have significantly improved cellular uptake and drug delivery across the BBB model.

Methodology: The synthesis of MNP was prepared by reverse-phase evaporation method. MNP-AZTTP was encapsulated into liposomes with fluorescent probe incorporation. This MNP-AZTTP was further characterized with respect to particle size, polydispersity index (PDI) and surface charge. The drug dissolution study was done through dialysis at different time intervals (30 min to 2 days) measured by HPLC. The initial in vivo characterization was carried out in mice by injecting MNPs through i.v. injection and retained within the 0.2 Tesla magnetic fields for 30min, 1hr, and 2hrs with anesthesia assistance.
At the end of the treatment, mice were sacrificed and brain tissues were harvested for co-localization studies of drug and MNP by fluorescent detection on frozen section slides of brain tissue.

**Results:** Preliminary data showed that MNP-AZTTP are of 118±15.2 nm size with 0.15 PDI and zeta potential of the particles was 10.3 ± 2.2 mV. Further, drug dissolution study displayed significantly sustained release property over free drugs. In vivo analysis indicated that within 2hr of injection the fluorescent MNP-AZTTP reached the brain while the signal from control group was negligible. Dose dependent study has revealed that 5mg/kg of MNPs are ideal for pharmacokinetics study in mice.

**Conclusions:** This novel formulation will be able to deliver multiple anti-HIV drugs more efficiently to rodent brain and also help us to detect the site of drug target in a noninvasive manner through imaging process.

**521LB A Novel Anti-HIV Particle Provides Sustained Plasma and Cell Drug Levels in Lymph Nodes in Primates**

**Jennifer Freeling**, Joseph Keath, Cailin Shu, Rodney JY Ho

**Background:** We have previously reported that an anti-HIV drug Indinavir bound to lipid nanoparticles (LNP) provide pH responsive release and extended plasma drug exposure and accumulation in lymph nodes in primates after subcutaneous dosing. The goal of this study is to develop and evaluate a HIV drug combination intended for a maximal suppression of residual virus. To do so we constructed an anti-HIV LNP containing two protease inhibitors [Lopinavir (LPV) and Ritonavir (RTV) and one nucleotide analogue reverse transcriptase inhibitor [Tenofovir (TNFV)] and compared the LNP versus free drug formulation for plasma time-course and intracellular drug levels in lymph nodes.

**Methodology:** The LNPs composed of lipids (DSPC: mPEG2000-DSPE) (8:2 m/m); and anti-HIV drugs-LPV, RTV and RNFV (115:10:5:15 lipids:LPV:RTV:TNFV m/m/m/m) were produced by solvent evaporation, followed by rehydration in buffered saline and homogenization with an Avestin Emulsiflex C5. Near-complete LNP incorporation of Lopinavir and Ritonavir and reproducible Tenofovir encapsulation (~5%) were verified. The anti-HIV LNP diameter was 50-80 nm. pH, osmolarity, and sterility were verified. Macaques (M. nemestrina) (n=4/gp) received free or LNP drug formulation subcutaneously. Blood and peripheral blood mononuclear cells (PBMCs) were collected for 24 hours and at day-7. The inguinal lymph node was collected at 24 hours and day-7. Drug concentrations were determined by liquid chromatography tandem mass spectroscopy (LC-MS/MS-QTRAP).

**Results:** Primates dosed subcutaneously with anti-HIV particles composed of LPV: RTV:TNFV at 25:14:17 mg/kg provided sustained plasma drug levels for more than 7 days. In contrast, animals treated with an identical dose in free and soluble form exhibited plasma and lymph node drug levels that decline rapidly below the detection limit by 24 hrs; and exhibited significant local skin reactions that persisted for more than 2 weeks. Animals that received LNP formulation did not exhibit local reaction. Treatment with anti-HIV LNP provided significant cellular drug concentrations at 24 hrs. In addition, mononuclear cells dissociated from lymph nodes also contained significant levels of LPV, RTV, and TNFV in the cells even 7 days after a single-dose anti-HIV LNP administration.

**Conclusions:** Anti-HIV lipid nanoparticles containing the three drugs, Lopinavir, Ritonavir and Tenofovir, demonstrated the ability of prolonged drug presence in plasma, PBMCs, and lymph node cells beyond levels achievable by free, non-particulate drug dosage form after a single subcutaneous administration in primates. Incorporation of the three drugs into LNP also reduced local side effects.

**522 NanoART Facilitated HIV-1 Clearance by a Mixed-Lineage Kinase 3 Inhibitor**

**Background:** Antiretroviral therapy (ART) has improved life quality and longevity for infected people. However, despite ART viral replication continues, albeit at low levels. Eradication of infection remains the major goal of HIV scientists and clinicians alike. Recently, a novel mixed-lineage kinase-3 (MLK3) inhibitor (URMC-099) with promising immune and neural modulatory activities was found. Surprisingly, the drug was found to potentiate the antiretroviral activities of our nanoformulated long-acting ART.

**Methodology:** Isobaric tag for relative and absolute quantitation (iTRAQ) was performed in URMC-099 treated monocyte-derived macrophages (MDM) seeking potential antiretroviral actions. Nanoformulated atazanavir (nanoATV) with/out dose escalated URMC-099 was tested for antiretroviral activities in HIV-1ADA exposed MDM. Viral DNA and RNA, Gag proteins and reverse transcriptase (RT) activities were assessed. Subcellular endosomal trafficking (Rab 5, 7, 8 and 14) of the ART nanoparticles were investigated by Western blot, confocal microscopy and HPLC. Humanized NOD/scid-IL-2Rγcnull (NSG) mice were infected with HIV-1ADA followed by administration of URMC-099 daily and nanoformulated atazanavir and ritonavir (nanoART/r) for three weeks beginning at 10 weeks post-infection. Peripheral viral load (VL), human CD4+ and CD8+ T cells, and lymphoid and brain tissues were investigated for virus and immune profiling.

**Results:** URMC-099 increased expression of the RAS-related GTP-binding proteins Rab 7, 8 and 14 in HIV-1 infected MDM. NanoATV antiretroviral activities were potentiated by URMC-099 with reductions in viral DNA and RNA, HIV-1gag and RT activity. URMC-099 increased ATV concentrations in Rab14 endosomal compartments. Highest levels of CD4+ T cells numbers were seen in infected humanized mice treated with URMC-099 and nanoATV with VL in plasma below the limit of assay detection in the mice (<500 copies/ml). Such URMC-099-ART synergy was not seen with native...
drug. Histopathological tests of spleen and lymph nodes showed decreased numbers of HIV-1p24 cells with both drugs as compared to nanoATV alone. Preservation of synaptic structures was also seen. iTRAQ and tandem mass spectrometry tests were confirmed by Western blot tests showing significant Rab7 and 8 changes in HIV-1 infected MDM.

Conclusions: URMC-099 significantly potentiates nanoATV responses to restrict HIV-1 and protect CD4+ T lymphocytes. This appears to occur, in part, by sustaining ART levels in specific endosomal compartments of the cells. Such new effects of URMC-099 may represent a novel means for viral clearance.

523 A Multiple Dose Study of Raltegravir (RAL) Formulations
Matthew L. Rizk, Rajesh Krishna, Valerie Schultz, Jolanda ten Bruggencate-Broeders, Patrick Larson, Larissa Wenning
Merck & Co., Inc., West Point, PA, United States

Background: ISENTRESS (raltegravir) is an integrase strand transfer inhibitor indicated in combination with other anti-retroviral drugs for the treatment of human immunodeficiency virus (HIV-1) infection. ISENTRESS is currently marketed as a 400 mg oral compressed tablet (OCT) formulation of raltegravir given twice daily for a total daily dose of 800 mg. This study was conducted to characterize the steady state pharmacokinetic (PK) profile of 1200 mg formulations of raltegravir to support once daily administration.

Methodology: An open label, multiple dose, randomized, three period, three treatment, crossover study was performed in 24 healthy male and female subjects (18 to 55 years). Subjects received either 1200 mg once daily (QD) of the OCT formulation (3x400 mg tablets), 1200 mg QD of a reformulated raltegravir (rRAL) formulation (2x600 mg tablets), or 400 mg twice daily (BID) of the OCT for 5 days. Safety and tolerability were assessed. Full PK profiles in all cases were collected after administration under fasted conditions on days 1 and 5. In pursuing a model based drug development approach, a PK/PD viral dynamics model is being utilized to assess the feasibility of these 1200 mg formulations for once daily dosing and inform future study design.

Results: RAL was found to be generally well tolerated in healthy subjects. Administration of 1200 mg OCT QD in the fasted state resulted in a day 5 geometric mean (CV%) Ctrough of 83.1 nM (53%), Cmax of 14.2 μM (99%), and AUC24hr of 49.3 μM-hr (73%). Similarly, administration of a 1200 mg rRAL tablet QD in the fasted state resulted in a day 5 geometric mean (CV%) Ctrough of 81.2 nM (72%), Cmax of 20.6 μM (44%), and AUC24hr of 59.4 μM-hr (34%). Administration of 400 mg OCT BID in the fasted state resulted in a day 5 geometric mean (CV%) Ctrough of 132 nM (56%), Cmax of 3.5 μM (153%), and AUC24hr (2xAUC12hr) of 26.0 μM-hr (106%).

Conclusions: Data from this study, in combination with other recently completed Phase I studies and PK/PD viral dynamics modeling and simulation, will be utilized to further assess whether QD dosing with these formulations would have a high likelihood of exerting antiviral activity similar to that of the current BID regimen, and provide insights into the feasibility of these formulations for once daily administration.

524 In Vivo Effects of Solid Drug Nanoparticle and Conventional Efavirenz On Anxiogenesis in Rodents
Paul Curley1, Marco Giardiello2, Neil Liptrott1, Philip Martin1, Tom McDonald2, Marco Siccardi1, Juliet McAdams3, Steve Rannard1, Tim Kirkham3, Andrew Owen1
1Molecular and Clinical Pharmacology, University of Liverpool, Liverpool, United Kingdom, 2Chemistry, University of Liverpool, Liverpool, United Kingdom, 3Institute of Psychology, Health and Society, University of Liverpool, Liverpool, United Kingdom

Background: Efavirenz (EFV) has variable bioavailability and induces neurocognitive side effects, including anxiety. Recently we reported an EFV solid drug nanoparticle (SDN) formulation with pharmacological benefits. Here we investigated neurocognitive disturbances in rats using the elevated plus maze (EPM) after administration of a conventional or SDN formulation. In this model, anxiety is typically demonstrated by time spent in the open arms versus the closed arms, with greater anxiety linked to less time on the open arms.

Methodology: Male Wistar rats were administered EFV (10mg/kg, 0.5% methylcellulose), SDN (10mg/kg) or vehicle control by oral gavage once daily for 5 weeks. Rats were placed in the EPM for 5 minutes weekly. Behavior was videotaped and analyzed using Ethowatcher software. Data were collected on number of entrances into the open and closed arms and time spent in the open arm, closed arm and central square (expressed as percentage of total time on EPM). Statistical analysis was performed by Mann-Whitney U test and significance was defined as P <0.05. All data are given as median [IQR].

Results: No differences in behavior were observed in week 1. In week 2, the percentage of time spent on the central platform was significantly increased in the EFV group (60% [51-65%]) compared to SDN (44% [25-50%]) and control (47% [34-57%]) with P = 0.03 and P = 0.91 for EFV and SDN versus control, respectively. The EFV group spent less time in the closed arm than the SDN group but this was not statistically significant. In week 3 differences in time spent on the central platform were again observed (EFV 65% [48-71%], SDN 31% [25-42%], control 46% [28-52%], with P = 0.01 and P = 0.28 for EFV and SDN versus control, respectively. Significant differences in the time spent in the closed arm were also observed (EFV 21% [13-46%], SDN 66% [47-75%], control 43% [33-71%]) with P = 0.005 and P = 0.631 for EFV and SDN versus control, respectively. Similarly in week 4, time spent by the EFV group on the closed arms was lower (EFV 34% [28-42%], control 61% [IQR 46-72%]; P = 0.005) and time on the central platform was higher (EFV 51% [46-57], control 30%, [26-42%]; P = 0.001). No statistically significant differences in behavior between any groups were observed in week 5.

Conclusions: Our experiment did not fully replicate EFV anxiogenic effects previously reported using the EPM, but did show clear behavioral effects indicative of CNS activity. Notably, a tendency of EFV to increase time spent on the central platform may be indicative of anxiogenesis. By contrast, the SDN did not consistently affect behavior in a manner that would indicate anxiogenic activity. We interpret these data as indicating the SDN may have reduced potential to induce neurocognitive disturbance, either acutely or after long-term administration.
Atazanavir/Cobicistat Fixed-Dose Combination Is Bioequivalent To the Separate Agents

Xiaolu Tao¹, Heather Sevinsky⁷, Reena Wang¹, Palanikumar Ravindran⁷, Karen Sims¹, Xiaohui Xu², Navin Jarwal¹, Richard Bertz¹
¹Bristol-Myers Squibb, Pennington, NJ, United States, ²Bristol-Myers Squibb, Princeton, NJ, United States

**Background:** The once-daily protease inhibitor atazanavir (ATV) boosted with low-dose ritonavir (RTV) and combined with other antiretrovirals is approved for the treatment of HIV-1 infection. Cobicistat (COBI), an alternative booster with more selective CYP3A inhibition but no antiretroviral activity or CYP induction, has similar pharmacoenhancing activity as RTV. A Phase III trial has demonstrated comparable efficacy and safety of ATV 300 mg + COBI 150 mg relative to ATV 300 mg + RTV 100 mg (85% vs 87% virologic suppression, respectively). To reduce pill and prescription burden, a fixed-dose combination (FDC) of ATV/COBI has been developed. Because ATV is recommended to be taken with food, which enhances ATV bioavailability and reduces pharmacokinetic variability, we assessed the bioequivalence of ATV and relative bioavailability of COBI in an FDC vs ATV and COBI coadministered individually after a light meal.

**Methodology:** This randomized, open-label, cross-over study in 64 healthy subjects assessed 48-hour ATV and COBI plasma concentration-time profiles after single doses of an FDC of ATV 300 mg/COBI 150 mg or ATV 300 mg and COBI 150 mg co-administered as individual agents (NCT01837719). Treatments were administered after a light meal and followed by a 7-day washout between each period. Pharmacokinetic (PK) parameters assessed were maximum plasma concentration (Cmax), area under the concentration-time curve to infinity and to the last time point with measurable able concentration AUC(0-T), and concentration at 24-hour post-dose (C24) for ATV. Bioequivalence for ATV was established if the 90% confidence intervals (CIs) for the FDC vs individual administration geometric mean ratios (GMRs) fell within the predefined limits of 0.80-1.25 for all PK parameters.

**Results:** All ATV PK parameter GMR 90% CIs fell within the predefined limits indicating bioequivalence of the FDC to ATV 300 mg and COBI 150 mg coadministered individually (Table). Although not prespecified, COBI in the FDC also met the criteria for bioequivalence to coadministration of the individual agents. Not unexpectedly with ATV, 5 subjects treated per protocol had total bilirubin elevations (1.2-2.1 × ULN), which were all improving or had resolved by study discharge.

**Conclusions:** ATV and COBI administered in an FDC is bioequivalent to coadministration of the individual agents under fed conditions. A single dose of ATV 300 mg and COBI 150 mg was safe and well tolerated when administered either as the FDC or as individual agents.

---

Non-Integrating Lentivirus Delivered CCR5-ZFNs Can Inhibit HIV-1 Infection in Humanized Mice

Guohua Yi, Jang-Gi Choi, Preeti Bharaj, Sojan Abraham, Manjunath Swamy, Premlata Shankar
Department of Biomedical Sciences, Center of Excellence in Infectious Disease, Texas Tech University Health Sciences Center, El Paso, TX, United States

**Background:** Zinc finger nuclease (ZFNs) technology is a powerful tool for therapeutic gene editing. CCR5 defective T cells are resistant to HIV-1 infection, so CCR5 disruption by ZFNs is a promising method for HIV-1 gene therapy. Successful clinical translation of the strategy will depend on the development of a safe and effective method for delivery of ZFNs into relevant cells. As permanent disruption of the targeted gene after a single ZFN treatment, Non-integrating lentivirus can provide a safe vehicle for delivery to avoid toxicity and off target expression associated with long-term expression. Further, HIV envelope can be used for pseudotyping, which enables the targeting of resting T cells, which are recalcitrant to transduction with conventional VSV-G pseudotyped lentivirus. Here we used non-integrating lentivirus with either HIV or VSVG envelope delivered CCR5-ZFNs into human resting T cells or primary hematopoietic stem cells respectively and investigated the disruption of CCR5 gene and protection of HIV infection in vitro and in humanized mice.
**Methodology:** ZFN constructs targeting both strands of CCR5 were connected via a 2A sequence, and then inserted to a lentivirus cloning vector. Chimeric non-integrating lentivirus (NILV) carrying CCR5-ZFNs was obtained by co-transfecting 293 T cells with intergrase-defective packaging plasmid and HIV (or VSVG) envelope plasmid. After transductions of different cell lines and primary T cells, as well as CD34+ Hematopoietic stem cells (HSCs), genomic DNAs were extracted for characterizing CCR5 disruption by CEL I assay. Thereafter, NILV transduced primary T cells or CD34+ stem cells were challenged with HIV – cnull, to test the protection of HIV infection in vitro. Protection from HIV challenge was tested in humanized NOD-scid IL2rgαβnull mice after adoptive transfer of NILV- transduced primary T cells (Hu/PBL model) or CD34+ stem cells (BLT model).

**Results:** The results showed that NILV carrying CCRS ZFNs transduced cell lines, primary T cells and CD34+ HSCs could successfully disrupt CCR5 gene with various levels of efficiencies, and that both activated and resting T cells transduced with ZFNs lentiviruses showed resistance to HIV infection in vitro. Furthermore, NILV transduced CD34+ could be reconstituted into BLT mice and, after HIV – cnull challenge, the CD4+ T cells count is maintained in the test group receiving ZFNs modified HSCs but not in controls. Likewise, endogenous virus replication was suppressed in NOD-scid IL2rgαβnull reconstituted with CCR5-ZFN transduced resting T cells from a HIV seropositive patient.

**Conclusions:** Non-integrating lentivirus provide a useful strategy for delivery of zinc finger nucleases for editing CCR5 and other therapeutically feasible host genes for HIV-1 gene therapy.

---

**527 Role of Sulphydryl in Causing Lytic Inactivation of HIV-1 by Env Targeting Peptide Triazole Thiols**

**Lauren D. Bailey,** Caitlin Duffy, Huyuan Li, Ali Emileh, Arangassery R. Bastian, Irwin Chaiken

1Biochemistry and Molecular Biology, Drexel University College of Medicine, Philadelphia, PA, United States, 2West Virginia University, Morgantown, WV, United States, 3Department of Infectious Diseases, The Scripps Research Institute, Jupiter, FL, United States, 4Biomedical Engineering, Drexel University College of Medicine, Philadelphia, PA, United States

**Background:** We have identified peptide triazole thiol inhibitors which bind Env gp120, allosterically inhibit CD4 receptor and co-receptor surrogate mAb 17b binding, and cause both gp120 shedding and p24 release from the virus lumen. The prototype peptide triazole thiol KR-13 (R-I-N-N-x-W-S-E-A-M-M-x-x-O-Q-x-B-A-C-C-x-NH2, x= ferrocenyltriazole-Pro) causes p24 release, however KR-13b (C-terminal SH capped by acetomidomethyl) inhibited cell infection but did not cause p24 leakage. We are investigating the mode of action by which the C-terminal sulhydryl group causes irreversible inactivation. From a molecular dynamics simulated model of the peptide triazole-gp120 complex we know that the IXW pharmacophore of KR13 binds in the CD4 binding site. Therefore, a working model is that the thiol interferes with conserved disulfides clustered proximal to the CD4 binding site in gp120 through “disulfide exchange”. These disulfides are located within gp120 at 296-331 (V3 loop), 385-418 (C4), 378-445 (C3), and 119-205 (V1/V2 loop).

**Methodology:** Peptide triazoles are synthesized by solid phase Fmoc chemistry, followed by click conjugation. Infectivity assays are performed with single round pseudo-typed HIV-1 BaL.01 and a luciferase gene, which is detected by chemiluminescence. p24 release was assayed using sandwich ELISA.

**Results:** To evaluate the importance of the spatial relationship between PT-SH and gp120 disulfide groups we synthesized truncated peptides derived from KR-13 and compared p24 release and antiviral activities. We observed a strong dependence of lysis activity on length of the linker between the IXW pharmacophore and SH group. We also examined the ability of KR13 to cause p24 release after HIV treatment with Ellman’s reagent, a disulfide exchange inhibitor. These results demonstrate that release of p24 induced by KR13 is significantly inhibited by Ellman’s reagent. Additionally, we have shown that 2G12, a conformational antibody which binds to a glycosyl group near the V3 loop, competes with the p24 release of virolytic peptides in a dose dependent manner.

**Conclusions:** We have shown that there is a discontinuous relationship between virolysis and peptide length, indicating that a minimal length is required for efficient virolysis. Our findings suggest that virolytic peptides disrupt the stable conformation of Env by interfering in disulfide exchange within gp120, thus sensitizing the viral membrane to rupture. Furthermore, our data implicates the V3 loop disulfide as a potential site that triggers this disulfide exchange cascade. We currently plan to investigate the functional cross-talk between the fusion mechanism and events leading to virolysis as well as examine the importance of specific Env disulfides that may be involved in disulfide exchange.

**528 eCD4-Ig Is a Highly Potent HIV-1 Entry Inhibitor**

Matthew Gardner, Lisa Kattenhorn, Jessica Chiang, Michael Farzan

1Department of Infectious Diseases, The Scripps Research Institute, Jupiter, FL, United States, 2Division of Comparative Pathology, Harvard Medical School, Southborough, MA, United States, 3Department of Microbiology and Immunobiology, Harvard Medical School, Boston, MA, United States

**Background:** Soluble CD4 and its more bioavailable form, CD4-Ig, neutralize HIV-1 less potently than most broadly neutralizing antibodies (bNAb)s because they bind the HIV-1 envelope glycoprotein with lower affinity and promote infection when cellular CD4 is limiting.

**Methodology:** We generated a fusion of CD4-Ig and a small CCR5-mimetic sulfopeptide (eCD4-Ig) and compared this fusion with CD4-Ig and the broadest and most potent bNAb s. We also investigated its properties in vivo.

**Results:** eCD4-Ig overcomes both shortcomings of CD4-Ig: It bound the envelope glycoprotein with higher avidity than CD4-Ig and its sulfopeptide inhibited infection promoted by CD4-Ig. eCD4-Ig efficiently neutralized a diverse panel of antibody-resistant tier 2 and tier 3 isolates without exception and with IC50 ranging from 0.002 to 1.137 μg/ml (0.02-11 nM) – values comparable to or better than those of the best HIV-1 bNAb s. Because it binds only conserved regions of the HIV-1 envelope glycoprotein, it is also broader than any bNab. Underscoring this breadth, it neutralized all forty isolates resistant to CD4-binding site bNAb s NIH45-46 and 3BCN117, as well as HIV-2 and antibody resistant SIV isolates, with IC50s from 0.001 to 1.453 μg/ml. eCD4-Ig also induced markedly more efficient antibody-dependent killing of HIV-1- or SIV-infected cells than did CD4-Ig and protected humanized mice from an HIV-1 challenge. Further, it retained its efficacy when delivered as an adeno-associated virus vector to three rhesus macaques, without eliciting an anti-eCD4-Ig antibody response.
**Conclusion**: eCD4-Ig is a highly potent, exceptionally broad, and mechanistically distinct inhibitor of HIV-1 entry that can be used to prevent or treat an HIV-1 infection.

529 **Computational Design of Novel Potent Inhibitors of HIV-1 Entry**

**Marina Tuyishime, Simon Cocklin**

Biochemistry, Drexel College of Medicine, Philadelphia, PA, United States

**Background**: The process of HIV-1 entry is key to the replication of the virus. It is one of the most attractive targets in the search for new drugs to treat HIV-1 infection as entry inhibitors would have utility in both pre- and post-exposure prophylaxis, including woman-controlled microbicides. In the HIV-1 entry field, two main inhibitor chemotypes predominate (BMS-377806- and NBD-556-type compounds) with the BMS-377806 analogues demonstrating superior potency. However, the BMS-377806 analogues suffer from poor solubility and oral bioavailability. Therefore, given the enormous potential of small molecule entry inhibitors, we have designed and tested a series of novel compounds that function as entry inhibitors and have better predicted ADME/PK properties.

**Methodology**: To identify novel compounds that function as entry inhibitors, we performed a high-content pharmacophore virtual screen using Blaze v10 (Cresset, UK) and a pharmacophore derived from templating BMS-377806, BMS-488043, and BMS-626529 using FieldTemplater v3.0 (Cresset, UK). 50 compounds were purchased for testing in the single round infection assay against HIV-1 pseudotyped with HIV-1 Env and AMLV Env. Spark v10 (Cresset, UK) and StarDrop v5.2 (Optibrium Ltd, UK) were employed to design a series of next generation compounds with novel scaffolds. Next generation compounds were synthesized and tested for potency and specificity in the single round infection assay.

**Results**: Assessment of the antiviral potencies and specificity of 50 commercially available screening compounds identified 5 novel compounds previously undescribed in the literature. However, each hit contained a core piperazine; a moiety that is shared by the BMS-377806-type inhibitors. Replacement of the core piperazine with a dipyrroline yielded a novel inhibitor with high micromolar potency. Sequential replacements of a terminal acenaphthene ring, with varying azaindole groups resulted in an inhibitor with low nanomolar potency. However, predicted ADME/PK properties remained poor. Replacement of the dipyrroline with a pyrrolo-3,4-pyrazole afforded a compound with improved predicted ADME/PK properties and that retained nanomolar potency.

**Conclusions**: Using a combination of high-content pharmacophore virtual screening, coupled with scaffold hopping by bioisotERIC replacements, and consideration of predicted ADME/PK properties, we have designed a new small molecule entry inhibitor with a novel scaffold, nanomololary potency, and improved predicted drug-like properties. This new chemotype may provide a blueprint for the future development of small molecule entry inhibitors, whilst characterization of its mechanism of action will yield important basic information about the process of HIV-1 entry.

530 **Cenicriviroc Achieves High CCR5 ReceptorOccupancy at Low NanomolarConcentrations**

Emilie Jalbert1, Mary Margaret Byron1, Cecilia Shikuma1, Helen Jenkins2, Eric Lefebvre2, Jason D. Barbour1

1University of Hawaii Manoa, Honolulu, HI, United States, 2Tobira Therapeutics, South San Francisco, CA, United States

**Background**: Cenicriviroc (CVC) is a novel, once-daily, potent, CCR5 and CCR2 antagonist that has completed Phase 2b evaluation for the treatment of HIV-1 infection in treatment-naive adults (NCT01338883). The aims of this study were to evaluate in vitro receptor occupancy and biology after treatment with CVC, BMS-22 (TOCRIS, a CCR2 antagonist) and an approved CCR5 antagonist, Maraviroc (MVC).

**Methodology**: PBMCs from 5 HIV+ and 5 HIV- subjects were incubated with CVC, BMS-22 or MVC, followed by either no treatment or treatment with a RANTES (CCR5 ligand) or MCP-1 (CCR2 ligand). The capacity of each drug to inhibit CCR5 or CCR2 internalization was evaluated. Cell-surface expression of CCR5 and CCR2 was assessed by flow cytometry, and fluorescence values were converted into molecules of equivalent soluble fluorescence (MESF).

**Results**: Both CVC and MVC, in the absence of RANTES, increased cell-surface expression of CCR5. This effect was seen to a much greater degree in HIV-negative subjects (CD4+ and CD8+ T cells). CVC prevented RANTES-induced CCR5 internalization at lower effective concentrations than MVC. The effective concentration at which saturation of CCR5 was reached for CVC was 3.1 nM for CD4+ and 2.3 nM for CD8+ T cells (~91% and ~90% receptor occupancy, respectively). MVC reached saturation at 12.5 nM for both CD4+ and CD8+ T cells, representing ~86% and ~87% receptor occupancy, respectively. CVC and MVC achieved high but incomplete saturation of CCR5, an effect that may be amplified by the observation of increased CCR5 expression with both agents in the absence of RANTES. In the absence of MCP-1, CVC induced CCR2 internalization and decreases cell-surface expression on monocytes. BMS-22 slightly increased CCR2 cell-surface expression. CVC prevented MCP-1-induced CCR2 internalization at lower concentrations than BMS-22. Saturation of monocyte CCR2 was reached at 6 nM of CVC, representing ~98% CCR2 occupancy. To reach >80% receptor occupancy, an average of 18 nM of BMS-22 was required, compared to 1.8 nM of CVC.

**Conclusions**: CVC more readily prevented RANTES-induced CCR5 internalization (at lower concentration) than MVC in vitro, indicating CVC more be more effective at preventing cellular activation by RANTES than MVC in vivo. Baseline CCR5 expression levels in treated subjects may be a determinant of CCR5 antagonist activity in vivo. CVC achieved ~98% receptor occupancy of CCR2 on monocytes at low nanomolar concentrations in vitro, and reduced CCR2 expression on monocytes in the absence of MCP-1. High saturation of CCR2 by CVC paired with reduced expression may explain the potent CCR2 blockade observed with CVC in the clinic. CVC has potent immunomodulatory activities in vitro, and may be an important combined immunotherapeutic and anti-retroviral in chronic HIV infection.
Preclinical Studies of Novel ART Approaches: Post-Entry

531 Identification of a Novel HIV-1 Inhibitor Targeting Vif-Dependent Degradation of Human APOBEC3G

Erez Perry1,2, Andrew Jay Brazier1, Ann Sheehy1, Vikas Miera1, Kottampatty S. Rajendran1,2, Marie K. Mankowski1, Lynn Rasmussen1, E. Lucile White1, Roger G. Ptak4, Dana Gabuzda1,6

1Cancer Immunology and AIDS, Dana Farber Cancer Institute, Boston, MA, United States, 2Department of Pathology, Harvard Medical School, Boston, MA, United States, 3Department of Biological Science, College of the Holy Cross, Worcester, MA, United States, 4Department of Infectious Diseases Research, Southern Research Institute, Frederick, MD, United States, 5High Throughput Screening Center, Southern Research Institute, Birmingham, AL, United States, 6Department of Neurology (Microbiology), Harvard Medical School, Boston, MA, United States

Background: APOBEC3G (A3G) is a cellular cytidine deaminase that restricts HIV replication by inducing G-to-A hypermutation in viral DNA and by deamination-independent mechanisms. Vif overcomes this innate antiviral activity by binding to A3G and targeting it for proteasomal degradation and by inhibiting its incorporation into virions. The interaction of Vif with A3G is essential for viral replication; as such, it represents a potential therapeutic target. Currently, there are no antivirals targeting Vif or its interaction with A3G.

Methodology: To identify compounds that inhibit interaction between A3G and HIV Vif in a high-throughput format, we developed a homogeneous time-resolved fluorescence resonance energy transfer (TR-FRET) assay. This assay detects the interaction between GST-Vif residues 1-94, which contains the A3G binding site, and a peptide consisting of A3G residues 110-148, a surrogate for the Vif binding site. A 307,520 compound library from the NIH Molecular Libraries Small Molecule Repository (MLSMR) was screened and 3686 hits were identified. To validate hits and eliminate false-positives, we employed a second TR-FRET-based assay and counter screen assays to evaluate dose response performance and off-target effects.

Results: In these primary and secondary screens, 310 hits were identified and then tested for antiviral activity against HIV-1Ba-L virus replication in human PBMC and in a cell-based screen for their ability to inhibit Vif-dependent degradation of A3G. These studies identified 3 compounds that demonstrated both antiviral activity against HIV replication in PBMC and attenuation of Vif-dependent degradation of A3G. One compound, N.41, showed antiviral activity in H9 T cells (A3G+) but not in SupT1 T cells (A3G-) and had an IC50 = 8.4 μM and TC50 >100 μM when tested against HIV-1Ba-L replication in PBMC. N.41 increased levels of A3G and its incorporation into virions in virus-producing cells, attenuated infectivity of single-round viruses in a Vif-dependent manner, and inhibited Vif-A3G interaction in co-immunoprecipitation assays. N.41 increased human but not African green monkey A3G levels in virus-producing cells in a Vif-dependent manner, and increased endogenous A3G levels in CEM T cells. Preliminary structure-activity relationship (SAR) studies suggested that a hydroxyl moiety located at the phenylamino group is critical for N.41 activity. Importantly, we identified several N.41 analogs with improved antiviral activities.

Conclusions: In this study, we identified a new lead compound that attenuates HIV replication by increasing A3G innate antiviral activity via liberating it from Vif regulation. SAR studies suggest that N.41 is a potential lead for further development as an antiviral.

532 Drugging HIV Vif as a Rational Approach To Eradication

Harold C. Smith, Ryan P. Bennett
OyaGen, Inc, Rochester, NY, United States

Background: The HIV auxiliary protein known as viral infectivity factor (Vif) enables HIV to overcome cellular APOBEC host-defense factors by binding to these proteins as a substrate receptor, thereby ensuring their ubiquitination and degradation through the 26S proteasome. Vif-Vif interaction through the PPLP domain has been shown to be ‘druggable’ in living cells using peptide mimetics. Disruption of Vif dimers inhibited live virus in spreading infection assays by protecting A3G from Vif-dependent degradation and enabled A3G incorporate in viral particles (Miller et al., (2007) Retrovirology 4:81-91).

Methodology: Live cell FRET for Vif dimerization in high throughput screening together with medicinal chemistry have identifying a small molecule Vif dimerization antagonist (SMVDA002-16) with low cytotoxicity and nM antiviral efficacy.

Results: Inhibition of HIV infection showed strict dependence on the expression of Vif and APOBEC3G. SMVDA002-16 enabled A3G antiviral activity by protecting A3G from Vif-dependent degradation, enhanced virion incorporation of A3G and inhibited viral replication. Analysis of integrated viral genomes for mutations in the pol gene in these studies following 48 hrs and 7 days of infection revealed extensive G to A hypermutation with numerous sense and nonsense codon mutations.
PF74 Inhibits Multiple HIV Capsid Functions Independent of Host Cyclophilin A and CPSF6

Stephen R. Yant1, Luong Trai1, Debi Jin1, Rajuta A. Bam1, Andrew Mulato1, Magdelaine Hung1, Chien-hung Chou2, Randall Halcomb1, Tomas Cihlar1
1Biology, Gilead Sciences, Foster City, CA, United States, 2Medicinal Chemistry, Gilead Sciences, Foster City, CA, United States

**Background:** HIV capsid (CA) is an emerging target for antiretroviral treatment. PF-3450074 (PF74) is a small-molecule CA binder that has been proposed to inhibit reverse transcription (RT) by accelerating HIV core uncoating. PF74 antiviral potency can depend on cyclophilin A (CypA) binding to CA in some cells and it shares a CA binding site with the host nuclear transport factor CPSF6, which restricts HIV infection when mislocalized to the cell cytoplasm. Here we further interrogate the mechanism of action (MOA) for PF74 in human T cells and clarify its potential dependence on CypA and CPSF6.

**Methodology:** HIV reporter viruses were produced in HEK293T cells and used to infect MT2 cells and primary CD4+ T cells to determine the antiviral effect of PF74. Compound exposure was controlled by staggered addition and cell washing at various times post-infection. DNA products of infection were analyzed by qPCR. CypA and CPSF6 levels were varied in MT2 cells by overexpression and shRNA knockdown. CA (P90A, N74D) and CPSF6 (FG 321AA) mutations were used to eliminate CypA or CPSF6 binding to the viral capsid. CPSF6 binding to CA was tested using a CA-NC pulldown assay.

**Results:** PF74 efficiently inhibited late (EC_{50} = 795 nM) and early (EC_{50} = 264 nM) post-entry stages of HIV-1 replication in single-round infectivity assays and stabilized CA-NC polymers in vitro. Stable CypA knockdown or mutation of the CypA binding site of CA (P90A) had no effect on HIV infectivity or PF74 antiviral potency in T cells. CypA-independence of PF74 MOA was confirmed in PBMCs using HIV isolates unable to bind CypA due to CA polymorphisms. Drug washout studies showed that at high concentrations (100x EC_{50}), PF74 inactivates cell-free virus via core disassembly and also acts concomitantly with the RT step in infected cells. At 10x EC_{50}, however, PF74 acted post-RT and was not virucidal, suggesting antiviral mechanism(s) beyond capsid destabilization. In time-of-addition studies, PF74 (10x EC_{50}) remained active when added after RT but before vDNA integration, and normal levels of late-RT products but reduced 2-LTR circles were observed under these conditions. In contrast, reduced late-RT products were detected at higher compound concentrations. Although PF74 did compete with CPSF6 binding to CA in vitro, it remained active against the N74D mutant virus that does not bind CPSF6, suggesting a CPSF6-independent MOA.

**Conclusions:** Although PF74 can accelerate viral capsid disassembly at high concentrations, our results indicate that this compound primarily acts after the RT step, but prior to 2-LTR circle accumulation in human T cells, via a CypA- and CPSF6-independent MOA. We propose that by directly stabilizing the viral capsid at lower drug concentrations, PF74 may interfere with nuclear targeting of the pre-integration complex.
536 Recent Progress in Developing Potent and Broadly Active HIV-1 Maturation Inhibitors

Emiko Urano1, Sherimay D. Ablan2, David Martin2, Ritu Gaur3, Paul W. Keller4, Alasadar C. Steven5, Theodore Nitz6, Carl Wild7, Eric O. Freed7

1HIV Drug Resistance Program, NCI-Frederick, Frederick, MD, United States; 2DH Pharma, Inc, Gaithersburg, MD, United States; 3South Asian University, New Delhi, India, 4National Institute of Arthritis and Musculoskeletal and Skin Diseases/NIH, Bethesda, MD, United States

Background: A betulinic acid-based compound, bevirimat (BVM), the first-in-class HIV-1 maturation inhibitor, acts by blocking a late step in protease-mediated Gag processing: the cleavage of the capsid-spacer peptide 1 (CA-SP1) intermediate to mature CA. BVM was shown in multiple clinical trials to be safe and effective in reducing viral loads in HIV-1-infected patients. However, single-amino-acid polymorphisms in the SP1 region of Gag resulted in variable response in BVM-treated patients, leading to the discontinuation of BVM’s clinical development.

Methodology: We carried out an extensive medicinal chemistry campaign to develop BVM derivatives that demonstrate not only increased potency against consensus clade B strains of HIV-1 but also that are active against isolates with polymorphisms in SP1 and primary, non-clade B isolates. Compound activity was tested in assays that measure CA-SP1 processing by radioimmunoprecipitation, single-cycle infectivity, cell-cell transmission, and virus replication kinetics. Long-term selection experiments were performed to identify mutations that confer resistance to these novel compounds. Compound binding to Gag was tested directly by using a tritium-labeled derivative. The effects of the compounds on virion morphology were examined at high resolution by cryo-electron tomography.

Results: We identified a set of BVM derivatives that are not only more potent than BVM against WT HIV-1 but also show robust antiviral activity against SP1 polymorphic strains and clade C isolates. These second-generation inhibitors are structurally similar to BVM with C28 heteroatom modifications. The best of these analogs displayed -3-log improved potency against polymorphic HIV-1 relative to BVM. Selection experiments identified a panel of resistant mutants that contain substitutions in Gag. The resistance mutations were analyzed for their effect on viral assembly, viral fitness, CA-SP1 processing, compound binding, and particle morphology. Cryo-electron tomography analysis demonstrated that HIV-1 maturation inhibitors act not only by blocking CA-SP1 processing but also by stabilizing the immature Gag lattice.

Conclusions: This study identifies a panel of C28 BVM derivatives that display marked improvements relative to BVM in their potency and breadth of activity. Biochemical, virological, and structural analyses performed with these compounds provide novel insights into the target and mechanism of action of HIV-1 maturation inhibitors. The results of this study provide novel insights into the structure of the maturation inhibitor-binding site and the role of SP1 in virus assembly and maturation. Finally, these findings suggest that clinical development of HIV-1 maturation inhibitors should resume.

RCTs in Second-Line ART and Virologic Failure

537 Mortality Among HIV+ Participants Randomized To Omit NRTIs vs. Add NRTIs in OPTIONS (ACTG A5241)

Karen Tashima1, Laura Smeaton1, Karin Klingman2, Adriana Andrade3, Joseph Eron4, Carl Fichtenbaum2, Rajesh Gandhi6, Victoria Johnson4, Richard Haubrich3

1Medicine, Warren Alpert Medical School of Brown University, Providence, RI, United States; 2Center for Biostatistics in AIDS Research, Boston, MA, United States; 3HIV Research Branch, TRP, DAIDS, NIAID, NIH, Bethesda, MD, United States; 4Medicine, Johns Hopkins University, Baltimore, MD, United States; 5Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 6Medicine, University of Cincinnati, Cincinnati, OH, United States

Background: OPTIONS enrolled treatment experienced participants with virologic failure who then started a new regimen after randomization to omit or add NRTIs. In the primary week 48 analysis, we found that omitting NRTIs was not inferior to adding NRTIs (CROI 2013, 153LB). In this analysis, we examined all-cause mortality.

Methodology: A5241 enrolled 360 subjects who had PI, NNRTI and NRTI experience and/or viral resistance. Personalized regimens with 3-4 ARVs (excluding NRTIs) having >2 active drugs, and NRTI combinations were selected; subjects were then randomized to add or omit NRTIs with the new regimen. All subjects were followed for 96 weeks for outcomes including mortality. Since mortality events were rare, exact logistic regression models using one covariate estimated exact odds ratios (eOR).

Results: During the screening process, when all subjects continued the failing NRTI-containing regimen (median duration 51 days), the mortality rate was 4.15/100 patient-years [p-y] (3 deaths). Following study entry and initiation of study treatment, there was only 1 death (0.31/100 p-y) among those omitting NRTIs (n=177); this participant died of trauma and pneumonia. Among those adding NRTIs (n=180), there were 10 deaths (3.1/100 p-y); these occurred at <24 wks (3), 24-48 wks (2), 48-72 wks (2), 72-96 wks (3) after study entry. Causes of death (with contributing factors) included heart failure (lymphoma) (1), cardiac disease (2), E. coli sepsis (liver failure, acute renal failure, HCV+) (1), cirrhosis (intra-abdominal bleed, HCV+) (1), listeria meningitis (1), pneumonia (2), PML (1) and renal failure (IRIS, hepatitis, autoimmune enteropathy) (1). All 10 add NRTI participants had initial virologic response to treatment.

Ability to identify factors associated with death is limited due to the rarity of events, especially by arm. VACS mortality index using baseline values was a significant predictor of mortality (eOR=1.9 per 10 unit increase. 95% CI = 1.3-2.8), whereas individual components of the index were not significantly associated: age (p=.17), hemoglobin (p=0.25), creatinine clearance (p=0.11), CD4 (0.91), HIV RNA (p=0.18), Hepatitis C (p=0.12).

Conclusions: In a randomized study that omitted vs. added NRTIs to new regimens, an unexplained imbalance in mortality was observed with only one death in the omit NRTI arm. Interpretation of the mortality difference is difficult because of the small number of events (11) and the potential for unmeasured confounders. The VACS mortality index was useful in predicting mortality in this treatment experienced population.
538 Partner-Based Intervention for Adherence To Second-Line ART: A Multinational Trial (ACTG A5234)

Robert Gross1, Lu Zheng2, Alberto La Rosa3, Xin Sun2, Susan Rosenkranz4, Sandra Cardoso-Wagner5, Francis Seali6, Robert Camp7, Catherine Godfrey8, Ann Collier9, ACTG Team A5234

1Medicine (ID), University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States, 2Biostatistics, Harvard School of Public Health, Boston, MA, United States, 3IMPACTA, Lima, Peru, 4FIOCRUZ, Rio de Janeiro, Brazil, 5Joint Clinical Research Centre, Kampala, Uganda, 6Eurodis, Barcelona, Spain, 7National Institute of Allergy and Infectious Diseases, Bethesda, MD, United States, 8University of Washington, Seattle, WA, United States

Background: Adherence is a fundamental determinant of antiretroviral therapy (ART) success. Some programs require patients to identify a support partner to enhance adherence. However, evidence supporting this strategy’s effectiveness is lacking.

Methodology: We conducted a 1:1 randomized trial of a treatment partner-based intervention compared with usual care for second-line ART at 9 low and middle income sites. Eligible patients were failing a non-nucleoside-based first-line regimen with HIV RNA >1000 copies/mL and had a willing support partner. The second-line regimen included lopinavir/ritonavir (400/100 mg) twice daily and emtricitabine/tenofovir disoproxil fumarate (200/300 mg) once daily. The intervention included one standardized partner training session focused on adherence support strategies and the partner observing and documenting one ART dose daily > 5 days/week for 24 weeks. Experimental partners were trained to implement adherence strategies and/or telephone the site for help if they observed non-adherence. Control partners received general HIV health information at entry with no additional support. The primary outcome was virologic failure (confirmed HIV RNA >400 copies/mL) at or prior to week 48; secondary outcomes included virologic failure at 24 weeks and adherence measured using electronic monitors (MEMS) summarized as % of doses taken quarterly (Q). The proportion of participants with failure was compared between groups using Fisher’s exact tests. Median adherence per quarter was compared using Wilcoxon rank sum tests.

Results: We enrolled 129 patients in the intervention and 126 in usual care, 130 (51%) males, 204 (79%) of African origin, 52 (20%) Latino, with a median age 38 years (interquartile range 33-45). Partners were parents (57, 22%), spouses (55, 21%), siblings (50, 19%), friends (41, 16%), and other (54, 21%). The proportions experiencing virologic failure at week 24 were 19% in the experimental arm vs.13% in the control arm, (p=0.31) and at week 48 were 26% in the experimental arm vs. 18% in the control arm, (p=0.13). Adherence by MEMS was similarly high [Q1: 96% vs. 96%, Q2: 91% vs. 94%, Q3: 90% vs. 93%, Q4: 91% vs. 93%] in experimental and control arms, respectively (all p=0.3).

Conclusions: We found no intervention effect on virologic responses or adherence. Potential reasons include control partners providing sufficient support without specific training, our single session being insufficient to significantly enhance skills, the study visits serving as a co-intervention that resulted in high adherence in the controls, or selection bias by enrolling highly adherent motivated volunteers. Continuing work is needed to identify interventions that can improve adherence in persons failing first line therapy.

539 Predictors of Late Virological Failure After Initial Successful Suppression On EFV-Based ART

Isaac Singini1, Thomas Campbell1, Laura Smeaton2, Nalageswaran Kumarasamy3, Karin Klingman4, Sineenart Taegaroenkul5, Timothy Flanigan5, Alberto La Rosa6, James Hakim7, Michael Hughes8, for the ACTG A5175/PEARLS Study Team

1Johns Hopkins Research Project, Blantyre, Malawi, 2University of Colorado Denver, Aurora, CO, United States, 3Harvard School of Public Health, Boston, MA, United States, 4YRGICARE Medical Centre, Chennai, India, 5NIH, NIAID, DAIDS, Bethesda, MD, United States, 6Chiang Mai University, Chiang Mai, Thailand, 7Minam Hospital, Brown University, Providence, RI, United States, 8Asociacion Civil Impacta Salud y Educacion, Lima, Peru, 9University of Zimbabwe College of Health Sciences, Harare, Zimbabwe

Background: There are practical issues, including high cost, in implementing virologic monitoring of patients on antiretroviral therapy (ART) in resource-limited settings. We evaluated factors that might guide less frequent virologic monitoring after successful virologic suppression on efavirenz (EFV)-based ART in such settings.

Methodology: HIV-1 RNA was measured every 8 weeks in antiretroviral naïve participants with nadir CD4 counts <300/mm³ who were randomized to EFV with lamivudine/zidovudine or emtricitabine/tenofovir in the international ACTG A5175/PEARLS trial, and who achieved HIV-1 RNA <1000 c/mL at 24 weeks without prior virologic failure or new AIDS event. Predictors of late virologic failure (late VF; confirmed HIV-1 RNA ≥1000 c/mL after 24 weeks) were evaluated by multivariate Cox models using stepwise selection from among the following variables: demographic; pre-ART CD4, HIV-1 RNA, AIDS, TB, hepatitis B, laboratory test results and body mass index; ART regimen; occurrence of Grade ≥3 laboratory results and signs/symptoms, ART change, self-reported adherence before week 24; and week 24 CD4 change and HIV-1 RNA (≥400 vs 401-999).

Results: 911 of 1045 subjects (87%) had HIV-1 RNA <1000 at 24 weeks. During median follow-up of >3yr after week 24, 82 of the 911 (9%) experienced late VF. VF rate appeared higher between 24 to 48 weeks (2.4%) but was reasonably constant thereafter (~1.25% every 24 weeks). In multivariate analysis, increased late VF risk was significantly associated with lower pre-ART hemoglobin (adjusted hazard ratio [AHR]=1.18 per 1g/dl lower; 95% CI: 1.04, 1.33; p=0.008), and both self-reported imperfect adherence (55/516 [10.7%] vs 27/413 [6.8%] for perfect adherence; AHR=1.72; CI: 1.08, 2.72; p=0.022) and absence of Grade ≥3 laboratory results prior to week 24 (77/800 [9.6%] vs 5/111 [4.5%] for those with Grade ≥3 results; AHR=2.53; CI: 1.02, 6.29; p=0.046). Sensitivity analyses restricted to subjects who did not change ART regimen, and to those without Grade ≥3 laboratories, prior to week 24 showed similar results. In time-updated analysis, self-reported imperfect adherence was a significant predictor of increased late VF risk.

Conclusions: In this clinical trial setting, the rate of late VF after successful suppression on EFV-containing ART was very low suggesting that virologic monitoring strategies involving infrequent (eg annual) measurements, possibly targeting subjects reporting imperfect adherence and those with lower pre-ART hemoglobin, might be considered; the implications of this for accumulation of resistance mutations needs evaluating. The unexpected finding that subjects without Grade ≥3 laboratory results before 24 weeks had higher risk of late VF needs evaluating further in a larger study.
540 Raltegravir Non-Inferior To Standard of Care in SECOND-LINE Therapy Over 96 Weeks

Janaki Amin, on behalf of the SECOND-LINE study team
The Kirby Institute, University of New South Wales, Sydney, Australia

Background: A regimen of lopinavir/ritonavir (LPV/r) and raltegravir (RAL) demonstrated non-inferior efficacy relative to a regimen of LPV/r with nucleoside/nucleotide reverse transcriptase inhibitors (N(t)RTIs) in primary analysis at 48 weeks. In this analysis we aim to assess durability of effect over 96 weeks.

Methodology: A total of 541 HIV-1 infected adults virologically failing first-line NNRTI+2N(t)RTI were randomised to receive RAL+LPV/r (RAL) or 2-3 N(t)RTI+LPV/r (N(t)RTI) in an open-label trial at 37 sites in Africa, Asia, Australia, Europe and Latin America. Eligibility criteria included no previous exposure to protease inhibitors (PI) and integrase strand transfer inhibitors (InSTI) and no active hepatitis B infection. Genotypic antiretroviral resistance testing (GART) was permitted. Differences between the proportion of participants with HIV-1 RNA (pVL) <200 copies/mL and <50 copies/mL by intention to treat were compared using chi-square statistics with a non-inferiority margin of -12%. Differences in biochemical, haematological and metabolic changes were assessed using T-tests.

Results: Participants were 55% male; 42% Asian; 36% African; and 14% Hispanic. At randomisation mean (sd) age was 38.8 (8.8) years, mean (sd) duration of 1st-line ART, 4.1 (2.8) years, mean (sd) plasma HIV-1 RNA, 4.2 (0.9) log copies/mL, and mean (sd) CD4+ T-cells, 211 (157) cells/mm^3. 3.7% patients withdrew or were lost to follow-up by week 96 (5.5% N(t)RTI vs. 1.9% RAL arm) and 19 patients died (11 in N(t)RTI arm vs. 8 in the RAL arm). In both arms 83% of participants remained on the randomized regimen through 96 weeks. pVL was <200 copies/mL at 96 weeks in 80.4% in the RAL arm and 76.0% in the N(t)RTI arm (difference: 4.4 [-2.6, 11.3]) and met non-inferiority criteria. Mean increases in CD4+ cell count (cell/mm^3) were similar in both arms. There were no differences in number of participants experiencing an adverse event or a serious adverse event; the RAL arm was associated with a significantly higher mean change in haemoglobin, lymphocytes, total cholesterol, HDL-cholesterol and LDL-cholesterol (Table 1).

Conclusions: At 96 weeks, an N(t)RTI-sparing second-line regimen of LPV/r+RAL continued to demonstrate similar efficacy, safety and tolerability compared to a regimen containing LPV/r+2-3N(t)RTIs. These results support the use of a combination PI and InSTI regimen as an option following failure of 1st line NNRTI+2N(t)RTIs.

541LB Randomized Comparison of Three Second Line ART Regimens in Africa: The 2 Lady/ANRS/EDCTP Study

Sinata Koulla-Shiro1, 2, Laura Ciaffi3, Vincent Le Moing3, Cheikh Tidiane Ndour4, Adrien Sawadogo5, Sabrina Eymard-Duvernay6, Avelin Aghokeng6, Jacques Reynes3, Alexandra Calmy7, Eric Delaporte8, on behalf of the 2LADY study group
1Service Maladies Infectieuses, Central Hospital Yaounde, FMSB/UY1, Yaounde, Cameroon, 2Site ANRS Cameroon, Yaounde, Cameroon, 3UM11233, IRD, Montpellier, France, 4Service Maladies Infectieuses, Hopital de Fann, CRDF, Dakar, Senegal, 5CHU Sanou Souro, HEU, Bobo Dioulasso, Burkina Faso, 6UM1233/IRD, IMPM/CREMER, Yaounde, Cameroon, 7Infectious Diseases, University Hospital Geneva, Geneva, Switzerland

Background: Access to antiretroviral therapy (ART) has increased significantly in the last decade: 9.7 million people were on ART at the end of 2012, 2.9% only on second line. WHO recommends the use of a ritonavir boosted Protease Inhibitor (PI/b) containing regimen in patients failing a Non-Nucleoside Reverse Transcriptase Inhibitor (NNRTI)-based first line, but evidence for the choice of combination is lacking.

541LB
**Methodology:** A 48 weeks, randomized, open label, non-inferiority trial in 3 African cities (Yaoundé - Cameroon, Bobo Dioulasso - Burkina Faso, Dakar - Senegal) comparing efficacy and safety of 3 second line regimens:

Arm A: tenofovir (TDF)/emtricitabine (FTC) + lopinavir/ritonavir (LPV/r), reference arm,

Arm B: abacavir (ABC) + didanosine (ddI) + LPV/r,

Arm C: TDF/FTC + darunavir/ritonavir (DRV/r).

Patients were eligible if above 18 years, failed a first line NNRTI based ART (confirmed HIV-1 RNA ≥ 1 000 copies/mL), showed good adherence (≥ 80%) and signed informed consent. Efficacy was defined as a HIV-1 RNA <50 copies/mL at 48 weeks and was analysed in both intention to treat (ITT-FDA snapshot) and per protocol (PP). Sample size was calculated for a power of 80% to show non inferiority with a margin of 15% and two-sided 95% confidence intervals.

**Results:** From January 2010 to October 2012, 454 patients were randomized. Participants were mainly women (72%), had been on ART for a median duration of 49 months (IQR 33- 69), had a median CD4 count of 183 cell/mm3 (IQR 87 - 290) and a median plasma HIV-1 RNA (VL) of 4.5 log10 (IQR 4 - 5.1). All but 6 had resistance to at least one first line drug and 95% to 2 classes.

At week 48 (cf table), 294 (65.2%) of the 451 analysed participants had an HIV-1 RNA<50 copies/mL, while 275 (83.2%) and 410 (90.9%) had a VL below 200 and 1 000 copies/mL respectively.

Primary results in ITT showed a difference of 5.6% (IC95% -5.1; 16.4) and 6.1% (IC95% -4.5; 16.7) between the reference arm A and arms B and C respectively, excluding non-inferiority. In multivariate analysis, VL ≤ 100 000 copies/ml at baseline was independent predictor of viral suppression.

No difference among arms was observed in median CD4 gain (+127 cells/µL), mortality or severe adverse events. No Protease mutations were observed in patients failing second line.

**Conclusions:** Despite multiple NRTI mutations, PI/b based second line regimens showed satisfactory results. However, results for patients with high viral load at switch to second line are of special concern. The WHO recommended regimen remains a valid option.

### Results for different VL thresholds and arm comparisons (with 95% CI)

**RCTs in First-Line ART in Treatment Naive Patients**

**542 First-Line Therapy With LPV/r vs NVP and 2 NRTIs in a Developing Country: W144 of a Randomized Trial**

Nathan Clumeck¹, Claude Mwamba², Kabamba Kabeya¹, Serge Matanda², Dolores Vaira³, Eric Kasamba², Coca Necoii³, David Kadiebwe², Chantal Milolo², Joe Ilunga², Lièvin Kapend⁴

¹Infectious diseases, CHU Saint-Pierre, Brussels, Belgium, ²Lubumbashi Network & PNMLS, Lubumbashi, Democratic Republic of the Congo, ³CHU Liége, Liége, Belgium

**Background:** In resource-limited countries, NNRTI-based regimen, as recommended by WHO, may result in emergence of more HIV drug resistance, because of a low genetic barrier. The purpose of the trial is to compare the efficacy and tolerance of LPV/r and NVP-based regimens and 2 WHO nucleoside backbones in naive HIV infected patients (p.).

**Methodology:** Naive p. from 5 clinics in Lubumbashi (Congo-RDC) were randomized to receive LPV/r tablets versus NVP combined with TDF/FTC or ZDV/3TC. VL and CD4 were performed at baseline (BL) and every 24 weeks (W). The primary endpoint was the % of p. with therapeutic failure defined as clinical and virologic failures (VL>1000 c/ml) (missing data=failure), assessed at W48 and 96. We present here the results of 144 W of follow-up.

**Results:** 425 Black African p. (72% female; median (md) age 38 years, md CD4 165/µL; md VL 5.2 log c/ml) were randomized (216 in LPV/r, 209 in NVP). BL characteristics were comparable. In the ITT analysis, previous results (abstract 88LB, CROI 2012) showed no difference between LPV/r and NVP.
treatment arms at W96 except a higher proportion of virologic failure (VF) in p. on NVP-based regimens. W144 ITT analysis showed a significant difference on endpoints between LPV/r (94/216) and NVP (111/209) (p=0.0479) and persistence of a significant difference in VF rate (20/216 vs 37/209 for LPV/r and NVP, respectively) (p=0.015). BL genotypes showed NNRTI mutations (mt) in 3/31 NVP-failing p. and no PI mt in LPV/r-failing patients. At time of failure, NNRTI mt were seen in 23/26 NVP-failing p. and 0/13 primary PI mt in LPV/r failing patients. NRTI mt were seen in 19/26 p. in NVP arm (including K65R in 7 p. and M184V in 18 p.) vs 3/13 p. in LPV/r arm (M184V in 3 p.).

Md CD4 change from BL was significant higher in LPV/r arm (251 cells/μL [interquartile range (IQR) 153;384]) compared with NVP arm (174 cells/μL [IQR 102-330]) (p=0.0093). There was no difference in adherence > 95% between groups (73.6 vs 74.4 for LPV/r vs NVP).

The discontinuation rate for toxicity was low: 2 p. (0.9%) in LPV/r and NVP groups. Hypersensitivity reactions were more frequent in the NVP (8/209) vs LPV/r (0/216) groups (p=0.0032). Diarrhea, nausea and vomiting were predominant with LPV/r (p<0.0001).

Md change from BL was significant higher for NVP + 20.5 ml/min [IQR 6.3;38.9] vs LPV/r +11.5[IQR -1;28.5] (p=0.0044) without significant difference between backbones.

Compared to BL, total cholesterol, LDL, HDL cholesterol, triglycerides and haemoglobin increased over time, but without significant difference between treatment groups.

**Conclusions:** In a resource-limited setting after 144 weeks of follow-up NNRTI-NRTI first-line regimen is associated with more virologic failure, more drug resistance mutations and a lower immunologic response than a PI-based regimen.

543 **Dolutegravir Regimen Statistically Superior To Tenofovir/Emtricitabine/Efavirenz: 96-Wk Data**

**Sharon Walmsley**1, Juan Berenguer2, Marie-Aude Khuong-Josses3, Michael Kity4, Thomas Lutz5, Daniel Podzamczer6, Norman Roth7, Catherine Granier8, Brian Wynne9, Keith Pappa10

1University Health Network, Toronto, ON, Canada, 2Hospital General Universitario Gregorio Marañón, Madrid, Spain, 3CHG – Hôpital Delfontaine, Paris, France, 4Medical University of South Carolina, Charleston, SC, United States, 5Infektologikum, Frankfurt, Germany, 6Bellvitge University Hospital, Barcelona, Spain, 7Prahaan Market Clinic, Melbourne, Australia, 8GSK, London, United Kingdom, 9GSK, Philadelphia, PA, United States, 10GSK, Research Triangle Park, NC, United States

**Background:** At the primary 48-Week analysis, Dolutegravir (DTG) 50 mg + abacavir (ABC)/lamivudine (3TC) once daily was superior to Tenofovir (TDF)/ Emtricitabine (FTC)/Efavirenz (EFV) in treatment-naive HIV-1 patients, with 88% vs 81% suppressed virologically (plasma HIV <50c/mL by snapshot algorithm [P=0.0033]); safety/tolerability was favorable for DTG + ABC/3TC. In order to access durability we now present 96 week final results.

**Methodology:** SINGLE (ING114467) is an ongoing Phase III, randomized, multi-center, double-blind, double-dummy study comparing the efficacy and safety of DTG plus ABC/3TC fixed dose combination (FDC) to TDF/FTC/EFV (ATR) in treatment-naive HIV patients. Randomization was stratified by baseline plasma HIV-1 RNA (≤ vs >100,000 c/mL) and CD4 cell count (≤ vs > 200 cells/mm3).

**Results:** 833 subjects were enrolled and treated (84% males; 32% non-white); treatment groups were similar at baseline. Through Week 96, 80% of DTG+ABC/3TC subjects and 72% of ATR subjects achieved <50 c/mL plasma HIV-1 RNA based on the FDA snapshot algorithm (difference 8.0%, 95% CI: +2.3%, +13.8% based on Cochran-Mantel-Haenszel analysis adjusted for strata), achieving pre-specified statistical superiority (P=0.006).

Differences in efficacy were primarily driven by a higher rate of discontinuation due to adverse events (AEs) in ATR recipients (11%), vs. 3% with DTG + ABC/3TC; most occurred prior to Week 48 (10% vs. 2%). Differences in time to viral suppression (28 vs 84 days; p<0.0001, generalized Wilcoxon test) and the change from baseline in CD4+ cells over 96 weeks (325 vs 281 cells/mm3, p=0.004, adjusted repeated measure model) both favored the DTG + ABC/3TC arm. DTG+ABC/3TC was better tolerated than ATR, with nervous system (23 vs. 50%, p<0.001) and psychiatric disorders AEs (32 vs. 40%, p=0.021) being more frequent with ATR, while insomnia was more frequent with DTG+ABC/3TC (17 vs. 11%, p=0.021, Fisher’s exact test). Few subjects experienced protocol defined virologic failure between Week 48 and 96 (occurrence increased from 4 to 6% of subjects in both arms). No treatment emergent primary integrase inhibitor (INI) or nucleoside reverse transcriptase inhibitor (NRTI) resistance mutations were observed through 96 weeks for subjects receiving DTG+ABC/3TC, while EFV and NRTI primary resistance mutations were observed in six and one patient respectively in the ATR group.

**Conclusions:** The DTG + ABC/3TC regimen resulted in potent and durable suppression of viral replication over 96 weeks, which was statistically superior to an ATR regimen. DTG + ABC/3TC maintained a favorable AE profile, with no treatment emergent primary INI or NRTI resistance mutations and a low rate of discontinuation due to virologic failure through 96 weeks.

544LB **A Randomized, Placebo-Controlled, Double-Blind Study of VM-1500 in HIV-Naïve Patients**

**Winal Ratanasuwan**1, Peerawong Werarak2, Robert L. Murphy3, Vadim Bichko4

1Preventive and Social Medicine, Faculty of Medicine Siriraj Hospital, Bangkok, Thailand, 2Northwestern University, Chicago, IL, United States, 3ChemDiv, Inc, San Diego, CA, United States

**Background:** VM-1500 is the pro-drug of the active compound VM-1500A, a potent, highly selective NNRTI. Its antiviral profile is superior to that of efavirenz and other currently marketed NNRTIs. The PK profile suggests once daily dosing. Together with minimal side effects, VM-1500 may be a good NNRTI to be started in HIV treatment.

**Methodology:** A randomized, placebo-controlled, multiple dose, double-blind study for 7 days in patients with HIV infection who are antiretroviral therapy-naïve with HIV-1 RNA > 5,000 copies/ml and CD4 > 250 cells/mm3. Eight patients were randomized to VM-1500 (20 mg) or placebo (7:1). After positive DSMB review the dose was escalated from 20 mg to 40 mg. A second cohort of 8 patients was randomized to VM-1500 (40 mg) or placebo (7:1).
Results: Seven patients who received 20 mg of VM-1500 for 7 days the average HIV-1 RNA decreased from 82,944 copies/ml to 2,133 copies/ml while one patient who received placebo, HIV-1 RNA was 303,000 copies/ml at day 1 and 248,000 copies/ml at days 8. The average CD4 increased from 551 cells/mm³ to 592 cells/mm³ in VM-1500 group and the CD4 of one patient in placebo arm was 492 cells/mm³ at day 1 and 517 cells/mm³ at day 8. For the second cohort with VM-1500 40 mg, 7 patients who received 40 mg of VM-1500 for 7 days the average HIV-1 RNA decreased from 93,671 copies/ml to 1,316 copies/ml while one patient who received placebo, HIV-1 RNA was 126,000 copies/ml at day 1 and 116,206 copies/ml at days 8. The average CD4 increased from 471 cells/mm³ to 525 cells/mm³ in VM-1500 group and the CD4 of one patient in placebo arm was 424 cells/mm³ at day 1 and 388 cells/mm³ at day 8. For the side effects, 3 patients in the first cohort (20mg) had mild dry mouth and polyuria, 1 patient had mild headache. However, patients in the second cohort (40mg) had no side effects for the whole seven days of VM-1500 treatment.

Conclusions: VM-1500 showed excellent activity with a 1.8 log reduction in HIV-1 RNA after 7 days of treatment with only minimal side effects. VM-1500 is a good once daily candidate NNRTI to treat HIV-infected patients.

545 The Oral Exam: A Simple Tool To Identify HIV-Infected Patients in Need of Antiretroviral Therapy
Ashita S. Batavia¹, Rode Secours², Patrice Espinosa¹, Marc A. Jean-Juste³, Patrice Severe², Jean W. Paper², Daniel W. Fitzgerald³
¹Department of Medicine, New York Presbyterian Hospital, New York, NY, United States, ²The GHESKIO Center, Port-au-Prince, Haiti, ³University of California San Francisco Medical Center, San Francisco, CA, United States

Background: Oral mucosal lesions that are associated with HIV infection can play an important role in monitoring the progression of disease, and can guide the decision to initiate antiretroviral therapy (ART). The discrepancies in the incidence of oral lesions, including AIDS-defining oral lesions, as a function of the timing of ART initiation has not been well characterized in the developing world. This information would be invaluable in better understanding how a simple clinical tool, the oral exam, can be used to predict the need for ART in resource-poor settings in which frequent CD4 T cell counts are not easily obtained.

Methodology: A randomized controlled clinical trial was conducted at the GHESKIO Center in Port-au-Prince, Haiti between 2004 and 2009. 816 HIV-infected ART-naïve participants with CD4 T cell counts between 200 and 350 cells/mm³ were randomized to either immediate ART initiation (early arm; N=408) or ART initiation when CD4 T cell count was less than or equal to 200 cells/mm³ (delayed arm; N=408). Every 3 months, all participants
underwent a comprehensive physical exam including an oral exam. All oral lesions were documented using Oral HIV/AIDS Research Alliance (OHARA) case definitions of oral disease endpoints.

**Results:** The frequency of oral disease endpoints in the delayed ART initiation arm was 2.98 times greater (N=164/408) than in the early arm (N=55/408). There was a significantly higher incidence of oral candidiasis, angular cheilitis, oral hairy leukoplakia and herpes labialis in the delayed arm. Recurrent intra-oral herpes simplex was twice as frequent in the delayed arm (N=8), and the average number of recurrences per patient was 2.5, as compared to 2 in the early arm. Of note, 8 patients in the delayed arm presented with AIDS defining oral conditions. Oral warts occurred 15 times in the delayed arm, but of these 66.7% occurred after ART initiation and the median time on ART was 177 days (range 110 to 738 days).

**Conclusions:** In our cohort, 40% of patients that delayed ART initiation developed an oral disease endpoint; this included 8 patients who presented with an AIDS-defining oral condition. In developing world settings, a routine oral exam is a simple and useful tool for identifying patients in need of initiating ART.

### 546 Efficacy of First-Line ARV Regimens: An Exploratory “Target Not Detected” Analysis

**Kirsten L. White**, Xuelian Wei, Lijie Zhong, Martin S. Rhee, Marshall W. Fordyce, Javier Szwarcb erg, John Mellors, Michael D. Miller

*Clinical Virology, Gilead Sciences, Inc, Foster City, CA, United States, University of Pittsburgh, Pittsburgh, PA, United States*

**Background:** Antiretroviral regimens aim to achieve undetectable HIV-1 RNA <50 copies/mL (c/mL). Below 50 c/mL, the Amplicor HIV-1 RNA v1.5 assay provides qualitative results, either "$<50$ c/mL (ie, HIV-1 RNA detected but not quantified), or "<50$ c/mL, No HIV-1 RNA Detected", referred to as “target not detected” (TND). Efficacy and TND of three first-line INSTI, NNRTI, and PI-based regimens in two phase 3 randomized, double-blinded clinical trials in HIV-1-infected, treatment-naïve adults were explored.

**Methodology:** Study 102: Evitegravir/cobicistat/emtricitabine/tenofovir DF (EVG/COBI/FTC/TDF) vs. efavirenz/FTC/TDF (EFV/FTC/TDF); Study 103: EVG/COBI/FTC/TDF vs. ritonavir-boosted atazanavir with FTC/TDF (ATV+RTV+TVD). Plasma HIV-1 RNA levels were assessed at all study visits through Week (W) 144 using the Roche COBAS Amplicor HIV-1 Monitor Test v1.5. All subjects in the ITT population from both studies were evaluated (n=1,408). Achievement of TND by treatment group and baseline characteristics was evaluated. P-values by two-sided Fisher’s Exact Test < 0.05 were statistically significant.

**Results:** Statistically more EVG/COBI/FTC/TDF subjects achieved TND than EFV/FTC/TDF from W2-W16 and from W2-W24 for ATV+RTV+TVD. However, after these time periods, TND levels were similar between treatment groups through W144 (Table 1). TND at W144 was more frequent in subjects with baseline HIV-1 RNA $\leq 100,000$ copies/ml and having adherence $\geq 95%$. Consistent and reproducible TND results were achieved and maintained at all visits from W48-W144 in approximately 15% of patients regardless of treatment group.

**Conclusions:** Subjects treated with EVG/COBI/FTC/TDF achieved HIV-1 RNA TND more rapidly than those treated with EFV/FTC/TDF or ATV+RTV+TVD. By W48 and through W144, TND was similar for all treatment groups. The clinical significance of achieving TND is uncertain. TND was associated with early initiation of treatment as suggested by lower HIV-1 RNA, consistent with recent treatment initiation guideline recommendations.

547 Randomized Comparison of Anthropometric Outcomes On EFV-Based Antiretroviral Therapies
Sineenart Taeranenkul1, Thomas Campbell2, Laura Smeaton3, Amita Gupta4, Nagalingeswaran Kumaramany5, Karin Klingman6, Isaac Singini7, Javier R. Lama8, Rosie Mingobisa8, Michael Hughes8, for ACTG A5175/PEARLS Study Team
1Chiang Mai University, Chiang Mai, Thailand, 2University of Colorado Denver, Aurora, CO, United States, 3Harvard School of Public Health, Boston, MA, United States, 4Johns Hopkins University, Baltimore, MD, United States, 5YRG CARE Medical Centre, Chennai, India, 6NIH, NIAID, DAIDS, Bethesda, MD, United States, 7Johns Hopkins Research Project, Blantyre, Malawi, 8San Miguel CRS, Lima, Peru, University of KwaZulu Natal, Durban, South Africa

Background: ACTG A5175/PEARLS was a randomized trial undertaken in diverse geographic settings that showed similar outcomes for the primary endpoint of time to virologic failure, new AIDS event or death in the comparison of tenofovir/emtricitabine or zidovudine/lamivudine with efavirenz (TDF/ FTC+EFV or ZDV/3TC+EFV). We present results for a secondary objective comparing the effects of these regimens on anthropometric outcomes.

Methodology: Antiretroviral naïve subjects with nadir CD4 counts <300/mm3 were enrolled in Brazil, Haiti, India, Malawi, Peru, South Africa, Thailand, United States and Zimbabwe, and randomized to TDF/FTC+EFV (n=526) or ZDV/3TC+EFV (n=519). We compared changes in weight, body mass index (BMI), and mid-arm, waist, hip and mid-thigh circumferences, from baseline to 48, 96 and 144 weeks using repeated measures intent to treat analysis

Results: 46% of subjects were female; median age, CD4 count and HIV-1 RNA were 34y, 159/mm3 and 5.0 log10 c/mL. Mean (sd) baseline anthropometric measures were: weight kg: 63 (14); BMI kg/m2: 23 (4); circumferences, cm: mid-arm 28 (4), waist 80 (10), hip 92 (10), mid-thigh 48 (7). 9% had BMI<18.5 (underweight); 21% had BMI>25 (obese). At weeks 48, 96 and 144: n=973, 941 and 902 had measurements; 35 subjects died and 106 were lost to follow-up before week 144. In both arms, there were significantly greater increases in all anthropometric measures at each weeks of 48, 96 and 144 (figure). The increases from baseline were, however, significantly larger for TDF/FTC+EFV vs ZDV/3TC+EFV (repeated measures p<0.001 except p=0.037 for waist) with mean change at week 144: weight kg: 4.8 vs 3.0; BMI kg/m2: 1.8 vs 1.1; circumferences, cm: mid-arm 1.7 vs 0.7, waist 5.2 vs 4.3, hip 3.8 vs 1.4, mid-thigh 3.1 vs 0.9. Difference in mean BMI change between arms did not vary significantly by baseline BMI: at week 144, -0.3 vs -0.8 kg/m2 for baseline BMI <18.5, 1.0 vs 0.7 for BMI 18.5-<25; 3.1 vs 2.1 for BMI ≥25.

There were 7 clinical diagnoses of lipoatrophy in the ZDV/3TC+EFV arm but none in the TDF/FTC+EFV arm.

Conclusions: Although the primary efficacy outcome was similar for TDF/FTC+EFV and ZDV/3TC+EFV, increases in weight, BMI and body circumferences were larger for TDF/ FTC+EFV. While these findings and the lower rate of clinical lipoatrophy for TDF/FTC+EFV support current guideline recommendations for TDF/ FTC+EFV as initial therapy, the greater BMI increases and hence potential for increased cardiovascular risk among overweight subjects needs consideration.

548 NEGR1 Genetic Variants and Risk for Virological Failure With Genotypic Resistance in Botswana
Sophie Limou1, Cheryl A. Winkler1, Hermann Bussmann2, 3, Vladimir Novitsky2, 3, Sihkuliile Moyo4, Max Essex4, 5, Richard G. Marlink2, 3, C. William Wester2, 4
1Center for Cancer Research, Basic Science Program, Frederick National Laboratory, Leidos BioMedical Research for the National Cancer Institute, Frederick, MD, United States, 2Department of Immunology and Infectious Diseases, Harvard School of Public Health, Boston, MA, United States, 3Botswana-Harvard School of Public Health AIDS Initiative Partnership for HIV Research and Education (BHP), Gaborone, Botswana, 4Vanderbilt Institute for Global Health (VIGH), Vanderbilt University School of Medicine, Division of Infectious Diseases, Nashville, TN, United States

Background: Access to antiretroviral therapy (ART) in sub-Saharan Africa has expanded due to a large number of national initiatives. Published findings from the Tshepo study previously demonstrated that NNRTI-assigned ART had no effect on the development of virological failure with genotypic resistance (VF/r) when evaluating persons randomized to receive nevirapine versus efavirenz-based ART. Here, we explore for the first time the impact of host genetic factors on the development of VF/r among ART-treated adults in Botswana.

Methodology: The Tshepo study is a 3-year randomized clinical study following 650 ART-naïve adults (64.9% female) from Botswana who initiated first-line NNRTI-based ART. 48 out of 650 (7.4%) enrolled study participants developed VF/r. We conducted a large-scale gene-centric association study on participants with sufficient DNA using the Illumina Human CardioMetabo1 chips enriched in markers for metabolic and cardiovascular genes (198K), including mitochondrial, ADME, renal, and immune response genes. After quality control, 133,822 SNPs were tested for association with VF/r in 46 cases

549LB Paradoxical Impact of Maraviroc/Raltegravir Added To HAART in Acute HIV Infection: ANRS 147 Trial

Antoine Chéret, Georges Nembot, Adeline Mélard, Camille Lécureux, Caroline Lascoux, Isabelle Ravaux, Jacques Reynes, Patrick Mailhes, Laurence Meyer, Christine Rouzioux

1EA 3620 Virology Laboratory, Université Paris-Descartes Sorbonne Paris Cité, Paris, France; 2Department of Infectious Diseases, DRON Hospital, Tourcoing, France; 3INSERM U1018, APHP Bicêtre Hospital, Faculty of Medicine Univ Paris-Sud, Le Kremlin-Bicêtre, Paris, France; 4INSERM U1012, Univ Paris-Sud, Paris, France; 5Department of Infectious Diseases, AP-HP, Saint-Louis Hospital, Paris, France; 6Department of Infectious Diseases, La Timone Hospital, Marseille, France; 7Department of Infectious Diseases, Guy de Chauliac Hospital, Montpellier, France, 8Department of Infectious Diseases, Croix Rousse Hospital, Lyon, France; 9INSERM U1018, Univ Paris-Sud, Paris, France

Background: Early HAART in acute HIV infection (PHI) is recommended at this period of generalized activation, the addition of maraviroc to boost CD4 increase and raltegravir for its potent antiviral effect should reduce HIV reservoirs and immune damage. The randomized multicenter OPTIPRIM-ANRS-147 trial was designed to evaluate the impact of an early 24-month treatment on total PBMC-associated HIV-DNA levels of raltegravir, maraviroc, darunavir/r and Truvada® (emtricitabine/tenofovir) (arm 1) compared to darunavir/r and Truvada® (arm 2).

Methodology: Inclusion criteria were: HIV-1 western-blot (WB) ≤ 4 antibodies and positive HIV-RNA, and CD4<500/mm3 in case of asymptomatic PHI. The primary endpoint was the between-arm difference in HIV-DNA level changes at M24. Clinical evaluation, HAART tolerance, CD4 count and activation, plasma HIV-RNA (VL) and HIV-DNA were analysed. At M24 HAART interruption was recommended if VL<50 cp/mL and CD4 ≥500/mm3 or ≥30%. Treatment resumption was further recommended if VL ≥50 000 cp/mL or CD4<500/mm3 and <30%.

Results: 90 patients were randomized 1/1 during 2010-2011, median age 35.5 years, 92% male; 96% had PHI symptoms (median time from symptoms onset 20 days [IQR:13-28]); 43% had HIV1 WB ≥1 Ab. At enrolment, median CD4, HIV-RNA, HIV-DNA values were 472 cells/mm3 [IQR: 386-640], 5.4 log10 cp/ml [4.9-5.8] and 3.7 log10 cp/106PBMC [3.4-4.0], respectively. Two treatment-related serious adverse effects occurred in arm 2 (pancreatitis,
At M24, a high impact of HAART on reservoir in arm 2 was observed, with an HIV-DNA change from baseline of -1.44 [-1.77; 1.03] log. However, the addition of raltegravir and maraviroc in arm 1 did not induce a higher decrease: -1.43 [-1.61; 1.23] (p=0.80); CD4 increase was similar in both arms. A paradoxical kinetic of VL was observed, with a higher decrease in arm 1 until M3 than arm 2 (60%<50cp/mL vs 31%, p=0.01) and conversely a significantly worse viral control in arm 1 vs arm 2 from M6 to M18: 71% vs 89%, 78% vs 96%, 82% vs 96% at M6, M12, M18, respectively. At M24, % of VL<50 cp/mL was similar in both arms, 91% vs 93%. We observed a trend towards lower decrease until M3 in CD4 activation (CD4/CD38+HLADR+): -1.7% arm 1 vs -2.9% vs arm 2 (p=0.09). The same difference was observed in patients with VL<50 cp/mL at M6. Lastly, 2 patients (1/arm) maintained VL<400 cp/mL year after treatment interruption, defining them as Post Treatment Controllers (PTC).

Conclusions: We report a strong impact of HAART on HIV-reservoirs in acute PHI patients, with 2 cases of PTC, but no additional benefit of this pentatherapy compared to guideline-recommended 3-drug therapy. Our hypothesis is that the versatile effects of maraviroc on immune cellular trafficking led to low level of viral replication thus limiting HIV reservoir decrease.

### 550LB Randomised Controlled Trial of a PI Monotherapy Switch Strategy for Long-Term HIV Management

**Nicholas Paton**¹,², Wolfgang Stohr¹, Alejandro Arenas-Pinto², David Dunn², the PIVOT Trial Group

¹National University of Singapore, Singapore, Singapore, ²MRC Clinical Trials Unit at UCL, London, United Kingdom

**Background:** Previous randomised trials show patients switching to PI monotherapy maintain high rates of viral load (VL) suppression over 48-96 weeks, sometimes meeting VL non-inferiority criteria. However, longer-term resistance and toxicity risks are uncertain and the place of PI monotherapy in long-term management therefore remains controversial.

**Methodology:** The Protease Inhibitor Versus Ongoing Triple-therapy (PIVOT) trial was a pragmatic 5-year prospective, randomised, controlled, open-label strategy trial in HIV-positive adults taking a stable NNRTI or PI-based regimen who had no previous VL failure and had VL<50 c/ml for ≥6 months at trial entry. Patients were randomised to maintain ongoing triple therapy (OT) or switch to a PI monotherapy strategy (PIm) using a (physician selected) ritonavir-boosted PI with prompt reintroduction of NRTIs if unable to maintain VL suppression <50 c/ml. VL was measured every 12 weeks, with resistance testing for all confirmed VL rebound ≥50 c/ml. Primary outcome was loss of future drug options, defined as new intermediate/high level resistance to ≥1 drug to which the patient’s virus was considered to be sensitive at trial entry. Secondary outcomes included serious disease complications (AIDS, serious non-AIDS, all-cause death), total grade 3/4 adverse events and neurocognitive function change (annual 5-test battery). All analyses were by ITT; non-inferiority margin 10%.

**Results:** We randomised 587 patients (77% male, 68% white, 53% on NNRTI regimen at baseline) at 43 UK sites. Median (maximum) follow-up was 44 (59) months; 2.7% withdrew or were lost-to-follow up. In PIm, 80% selected DRV/r, 14% LPV/r, 7% other PI/r. VL rebound was much more common in PIm; all rebounds on monotherapy re-suppressed either spontaneously or with NRTI reintroduction. Sequences were obtained for 83% of confirmed VL rebounds, but few new resistance mutations were seen in either arm. PIm was non-inferior on the primary outcome of loss of future drug options and there were no significant differences in serious disease complications, adverse events or neurocognitive function between the arms. 58% in PIm remained on monotherapy at the end of trial and overall drug costs were substantially lower in this arm.

**Conclusions:** PI monotherapy, with prompt reintroduction of NRTIs for VL rebound, was a successful long-term management strategy, preserved future treatment options, was safe and well tolerated, and may be considered for more widespread use in long-term HIV care.

| Table 1. Number of patients with event, mean change in CD4 count or neurocognitive function, and mean costs - all during period from baseline to end of follow up. |

**551LB Simplification of PI+RTV+FTC/TDF To E/C/F/TDF Maintains HIV Suppression and Is Well Tolerated**

Jose Arribas1, Gilles Pialoux2, Joseph Gathe3, Giovanni Di Perri4, Jacques Reynes5, Pablo Tebas6, Thai Nguyen7, Ramin Ebrahimi7, Kirsten White7, David Piontkowsky7

1Hospital La Paz, Madrid, Spain, 2UPMC, Hôpital Tenon APHP, Paris, France, 3Baylor College of Medicine, Houston, TX, United States, 4University of Torino, School of Medicine, Torino, Italy, 5Gui de Chauliac University Hospital, Montpellier, France, 6University of Pennsylvania, Philadelphia, PA, United States, 7Gilead Sciences, Inc., Foster City, CA, United States

**Background:** Antiretroviral (ARV) regimen simplification can improve treatment adherence and quality of life. We report the Week (W) 48 results of a prospective, randomized, open-label, ongoing Phase 3b trial of a regimen simplification to the single-tablet regimen elvitegravir/cobicistat/emtricitabine/tenofovir DF (E/C/F/TDF) from ritonavir-boosted protease inhibitor (PI+RTV) plus emtricitabine/tenofovir DF (FTC/TDF) regimens.

**Methodology:** Virologically suppressed subjects on PI+RTV + FTC/TDF regimens for ≥6 months were randomized (2:1) to switch to E/C/F/TDF or remain on their baseline PI regimen (i.e. PI). Eligibility criteria included CrCl ≥70 mL/min, no documented resistance to FTC and TDF, exposure to no more than 2 prior ARV regimens, and no history of virologic failure. The primary endpoint was the proportion of subjects who maintained HIV-1 RNA < 50 c/mL at W48 by FDA snapshot algorithm (12% noninferiority margin). If noninferiority was established, then superiority would be tested per a prespecified sequential testing procedure.

**Results:** A total of 433 subjects (86% male, 19% non-white, 18% age ≥50 years) were randomized and treated (293 E/C/F/TDF; 140 PI). At randomization, RTV-boosted atazanavir (40%) and RTV-boosted darunavir (40%) were the most common PIs used; median years since first ARV use was 3; 19% were on their second ARV regimen. Baseline characteristics were similar between the two groups. At W48, 94% of subjects on E/C/F/TDF maintained HIV-RNA < 50 c/mL compared to 87% on PI (difference 6.7%, 95% CI +0.4% to +13.7%; p=0.025). Rates of virologic failure were low (0.7% E/C/F/TDF vs 1.4% PI) with no emergent resistance in either group. The safety and tolerability profiles of E/C/F/TDF were consistent with those reported in previous studies. Grade 2-4 drug-related adverse events (AEs) were 3.8% E/C/F/TDF vs 1.4% PI. AEs leading to drug discontinuation were low, 2.0% vs 2.9% respectively. At W48, median changes in CrCl (mL/min) were -7.5 and 0.4, respectively, with no cases of proximal renal tubulopathy in either group. There was a larger decrease from baseline in fasting triglycerides for E/C/F/TDF compared to PI (median: -16 vs +3 mg/dL; p =0.001) and no change in other lipid parameters.

**Conclusions:** Switching to E/C/F/TDF compared to continuing PI+RTV+FTC/TDF resulted in significantly higher rates of virologic suppression without emergence of resistance. E/C/F/TDF was well-tolerated with a favorable safety profile. Switching to E/C/F/TDF from a multiple-tablet, PI-based regimen may be an option for patients wishing to simplify their ARV therapy.

---

**552LB Effect of Selenium Supplementation On CD4 Depletion in Rwandan HIV Patients: A Randomized Trial**

1Stanford Prevention Research Center, Rwanda Biomedical Centre, Kigali, Rwanda, 2Rwanda Biomedical Center, Kigali, Rwanda, 3Rwanda Supplementation Study Team, Kigali, Rwanda, 4University of British Columbia, Vancouver, BC, Canada, 5Wilfrid Laurier University, Windsor, ON, Canada, 6Stanford Prevention Research Center, Stanford University, Stanford, CA, United States

**Background:** Micronutrient deficiencies occur early in human immunodeficiency virus (HIV) infection and are associated with accelerated disease progression. We aimed to determine if long-term selenium supplementation is effective and safe in delaying CD4 T-cell decline and disease progression when implemented early in adults infected with HIV who are antiretroviral therapy (ART) naïve in Rwanda.

**Methodology:** We randomized patients in a multi-centre, patient and provider-blinded, randomized, placebo-controlled clinical trial involving ART naïve HIV-infected patients. We recruited patients ≥21 years of age with documented HIV infection and CD4 cell count of 400-650 cells/mm3, and not yet on ART. Patients received selenium 200 mcg per day or matching placebo. The primary outcome is change in CD4 T-cell status between groups. Secondary outcomes include a composite of CD4 depletion to 350 cells/, or start of ART, or the emergence of a documented CDC-defined AIDS-defining illness; viral suppression; mortality; and
adverse events. We applied an intent-to-treat analysis. Linear regressions with generalized estimating equations and effect modification was used for the primary outcome.

**Results:** 151 patients received selenium and 149 placebo arm, with an average baseline CD4 of 555 cells/mm3. Seventeen patients were lost to follow-up. One non-AIDS death occurred in each group. Twenty-three women were time censored due to pregnancy and placed on ART. The rate of CD4 depletion was reduced by 43.8% among patients receiving selenium (95% confidence interval [CI]: 7.8-79.8% reduced). Figure 1 displays the CD4 change over 24 months. Average declines in CD4 over the trial period were 54 cells among the selenium arm and 95 cells among the placebo arm. In total, 96 events for the composite outcome were observed, with 45 (47%) in the treatment arm. We found no treatment effect for the composite outcome (hazard ratio 1.00, 95% confidence intervals [CIs] 0.66 - 1.54) or viral suppression (odds ratio, 1.18, 95% CI 0.71 - 1.94). We found no significant differences between groups for adverse events.

**Conclusions:** In ART-naive HIV-infected adults, 24-month selenium supplementation was safe and significantly decreased the rate of immune decline. Selenium supplementation may be an inexpensive and effective intervention when started in the early stages of HIV disease.

### 553LB Switch From NNRTI plus FTC/TDF To E/C/F/TDF Maintains HIV Suppression and Is Well Tolerated

Anton Pozniak1, Martin Markowitz2, Anthony Mills3, Hans-Juergen Stelbrink4, Antonio Antela5, Pere Domingo6, Pierre-Marie Girard7, Keith Henry8, Wil Garner9, Bill Gayer10

1Chelsea and Westminster NHS Foundation Trust Hospital, London, United Kingdom, 2Aaron Diamond AIDS Research Center, New York, NY, United States, 3Anthony Mills MD Inc., Los Angeles, CA, United States, 4ICH Study Center, Hamburg, Germany, 5Hospital Clinico Universitario, Santiago de Compostela, Spain, 6Hopital de la Santa Creu i Sant Pau, Barcelona, Spain, 7Hopital Saint-Antoine, Paris, France, 8Hopital Saint-Antoine, Paris, France, 9Gilead Sciences, Inc., Foster City, CA, United States

**Background:** Concerns with current and/or long-term side effects or dosing complexity of antiretroviral (ARV) regimen may prompt patients to request ARV switches. We report the Week (W) 48 results of a prospective, randomized, open-label, ongoing Phase 3b trial of a regimen switch to the single-tablet regimen (STR) elvitegravir/cobicistat/emtricitabine/tenofovir DF (E/C/F/TDF) from non-nucleoside reverse transcriptase inhibitor (NNRTI) + emtricitabine/tenofovir DF (FTC/TDF) regimens in virologically-suppressed HIV-1 subjects.

**Methodology:** Subjects suppressed on NNRTI + FTC/TDF regimens for ≥ 6 months were randomized (2:1) to switch to E/C/F/TDF or remain on their baseline NNRTI regimen (i.e. NNRTI). Eligibility criteria included CrCl ≥ 70 mL/min, no documented resistance to FTC and TDF, exposure to no more than 2 prior ARV regimens, and no history of virologic failure. The primary endpoint was the proportion of subjects who maintained HIV-1 RNA < 50 c/mL at W48 by FDA snapshot algorithm (12% noninferiority margin).

**Results:** A total of 434 subjects (93% male, 22% non-white, 22% age ≥ 50 years) were randomized and treated (291 E/C/F/TDF; 143 NNRTI). At randomization, 78% of subjects were on an efavirenz (EFV)-based regimen (74% on STR EFV/FTC/TDF); median years since first ARV use was 3; and 31% enrolled in the study due to concern with current or long-term side effects of their ARVs. Baseline characteristics were similar between the two groups. E/C/F/TDF was noninferior to NNRTI regimens, as 93% and 88% respectively maintained virologic suppression at W48 and at W48 (difference 5.3%, 95% CI -0.5%, +12.0%). Virologic failure rates were 1% with no emergent resistance detected in either group. The safety and tolerability profiles of E/C/F/TDF were consistent with reports from previous studies. Grade 2-4 drug-related adverse events (AEs) occurred in 5.5% E/C/F/TDF and 1.4% NNRTI. AEs leading to discontinuation were low (2.1% E/C/F/TDF vs 0.7% NNRTI). Median changes in CrCl (mL/min) at W48 were, as expected, -11.6 and -0.2 respectively. Small decreases from baseline in total, LDL, and HDL cholesterols were experienced by those switching from EFV-based regimens. Decreases from baseline at W48 in rates of neuropsychiatric symptoms, e.g. vivid dreams (-15%, p <0.001), dizziness (-11%, p <0.001), anxiety (-9%, p =0.008), and insomnia (-10%, p =0.004), were reported after switching to E/C/F/TDF [HIV Symptom Index]. HIV Treatment Satisfaction scores were higher for subjects who switched to E/C/F/TDF (p <0.001) [HIV Treatment Satisfaction Questionnaire].

**Conclusions:** Switching to E/C/F/TDF from NNRTI + FTC/TDF regimens was associated with high rates of virologic suppression, no resistance development, and favorable tolerability with improved treatment satisfaction.

### 554 Blunted Response To cART in Elite Controllers

Farouy Boufassa1, Jerome Le Chenadec2, Laurence Meyer3, Dominique Costagliola3, Peter W. Hunt4, Florencia Peryoya5, Steve Deeks6, Gianfranco Pancino7, Olivier Taulera8, Mathias Lichterfeld8, Pierre Delobel9, Asier Saaz-Cirion10, Olivier Lambotte11

1Epidemiology, INSERM U1018, Univ Paris Sud, Le Kremlin-Bicetre, France, 2Epidemiology, INSERM U1018, Le Kremlin-Bicetre, France, 3Epidemiology, INSERM U1018, AP-HP, Univ Paris Sud, Le Kremlin-Bicetre, France, 4UPMC Univ Paris 06, INSERM UMR 943, Paris 75013, France, 5Department of Medicine, University of California San Francisco, San Francisco, CA, United States, 6The Ragon Institute, Cambridge, MA, United States, 7Institut Pasteur, Paris 75015, France, 8Hopital Saint Louis, Paris 75010, France, 9Division of Infectious Diseases, Massachusetts General Hospital, Boston, MA, United States, 10Service des Maladies Infectieuses et Tropicales, INSERM UMR1043, Toulouse, France, 11Service de Medecine Interne, AP-HP, Le Kremlin-Bicetre, France

**Background:** HIV Elite Controllers (ECs) spontaneously control viral load. Some EC however initiate anti-retroviral treatment (cART), due to loss of viral control or CD4 T cell (CD4Tc) decrease. The CD4Tc dynamics in Controllers on cART has been poorly described. Here we studied the CD4Tc dynamics after cART initiation among 34 EC followed in US and Europe cohorts, compared to viremic infected patients (VIRs).
**Methodology:** ECs were defined as having ≥ 5 viral load (VL) measurements <400 copies/mL over ≥5 years while never having received ART and were identified from the French ANRS CO18 Cohort, the US SCOPE Cohort, the International HIV Controllers study and the European CASCADE collaboration. VIRs were selected from the ANRS COPANA Cohort which enrolls ART-naïve recently-diagnosed (<1 year) HIV-1-infected adults. Dynamics of CD4Tc counts after cART initiation were modelled by piecewise mixed linear models.

**Results:** In VIRs, CD4Tc increase after cART initiation followed a 2-stage pattern: an initial rapid increase over the first 3 months (+0.63 sqrt(CD4)/month), followed by a slower increase of +0.19 sqrt(CD4)/month. This contrast with treated ECs where no such rapid first slope was observed: the CD4 increase was moderate and similar to the second slope observed in VIRs. For a patient starting cART at 300 CD4Tc, mean gain in the first 12 months were 139 for VIRs vs. only 80 for ECs (p=0.048).

**Conclusions:** This is the largest series of treated ECs. ECs who initiate cART experience an increase in CD4Tc counts, although lower than that achieved by VIRs.

**555 Viral Set Point After Cessation of Antiretroviral Therapy Initiated in Acute Primary HIV Infection**

Christine Durier1, Cécile Goujard2, a, Caroline Roussillon3, a, Isabelle Fourrier1, Catherine Fagard4, a, Isabelle Charreau, Gilles Pialoux5, a, Bruno Hoerauf6, a, Christine Rouloux7, a

1INSERM SC10-US019, Villejuif, France, 2Hôpital Bicêtre, Kremlin-Bicêtre, France, 3Université Paris-Sud, Kremlin-Bicêtre, France, 4Université de Bordeaux, Bordeaux, France, 5INSERM U997, Bordeaux, France, 6Hôpital Tenon, Paris, France, 7Université Pierre et Marie Core Paris 06, Paris, France, 8Université Antilles-Guyane, Pointe-à-Pitre, France, 9University Hospital of Guadeloupe, Pointe-à-Pitre, France, 10Hôpital Necker, Paris, France, 11Université Paris Descartes Paris 05, Paris, France

**Background:** Antiretroviral therapy (ART) is increasingly offered to persons with primary HIV infection (PHI) to improve the course of HIV disease. To identify among individuals treated during PHI those who will be able to control viral replication after cessation of ART is important from the dual perspective of clinical management and identification of mechanisms of viral control.

**Methodology:** Data from 112 participants in ANRS 100 (n=26) and ANRS 112 (n=86) trials who received 18-month ART initiated in acute PHI and underwent a scheduled treatment interruption were pooled for analysis. Logistic regressions were used to identify factors associated with a plasma HIV-1 RNA (VL) level <1000 cp/mL 6 months after cessation of therapy (viral set point). Median (interquartile range) results are presented.

**Results:** Median age was 34 years (29-41); 13 (12%) were women. Before treatment initiation, CD4 T cell count was 425 cells/mm3 (299-607), VL and total cell associated HIV-1 DNA levels were 5.7 log10 cp/mL (5.0-5.9) and 3.5 log10 cp/106 PBMC (3.0-3.7), respectively and number of Western blot antibodies was 2 (1-3). At completion of 72-84 weeks of treatment, VL was <50 cp/mL in 83/108 (77%) patients, CD4 T cell count had increased to 682 cells/mm3 (556-852) and HIV DNA decreased to 2.3 log10 cp/106 PBMC (1.8-2.7).

Six months after ART interruption, median VL was 3.9 log10 cp/mL (3.0-4.3). VL was <1000 cp/mL in 26 patients (23%, 9/13 women and 17/99 men) and <50 cp/mL in 7 patients (6.2%, 4/13 women and 3/99 men, p=0.003 Fisher’s exact test). Female sex and a low baseline VL were significantly associated to a low viral set point; a high CD4 T cell count at baseline showed a trend. Patient’s age, trial number of Western-blot antibodies, CD8 T cell count at baseline, HIV DNA level at baseline and at treatment interruption were not associated with viral set point. In multivariate analysis, female sex was the only variable significantly associated to an increased likelihood of VL <1000 cp/mL (p=0.02). Considering men only (n=99), 17% achieved a VL <1000 cp/mL 6 months after interruption and no predictive factor of viral set point was identified among CD4 T cell count, VL or HIV DNA level at initiation or at 18 months of treatment.

**Conclusions:** Women were more likely to control viral replication than men. After adjustment on sex, no other pretreatment or end-of-therapy characteristic was identified in this population to predict a low or undetectable VL 6 months after cessation of ART. This difference between men and women deserves further investigation.

**556 HIV Elite Controllers Are Hospitalized More Often Than Persons With Medically Controlled HIV**

Trevor A. Crowell1, a, Kelly A. Geho2, b, Joel N. Blankson3, a, Baligh R. Yehia4, a, Richard M. Rutstein5, a, Stephen A. Berry3, a

1INSERM SC10-US019, Villejuif, France, 2Hôpital Bicêtre, Kremlin-Bicêtre, France, 3Université Paris-Sud, Kremlin-Bicêtre, France, 4Université de Bordeaux, Bordeaux, France, 5INSERM U997, Bordeaux, France, 6Hôpital Tenon, Paris, France, 7Université Pierre et Marie Core Paris 06, Paris, France, 8Université Antilles-Guyane, Pointe-à-Pitre, France, 9University Hospital of Guadeloupe, Pointe-à-Pitre, France, 10Hôpital Necker, Paris, France, 11Université Paris Descartes Paris 05, Paris, France

**Background:** Among adults engaged in care 2005-2011 at 12 HIV Research Network sites, we identified person-years (PY) with CD4 consistently >350 cells/mm3 and categorized each PY as EC, MC, or UC. EC was defined by ≥5 viral load (VL) measurements <400 copies/mL over ≥12 months in the absence of antiretroviral therapy (ART). MC required the same HIV RNA parameters with use of ART. All other PY were considered UC. Progression out of EC or MC status occurred if ≥12 undetectable HIV RNA values over ≥12 months in the absence of antiretroviral therapy (ART). MC required the same HIV RNA parameters with use of ART. All other PY were considered UC. Progression out of EC or MC status occurred if ≥12 undetectable HIV RNA values over ≥12 months in the absence of antiretroviral therapy (ART). MC required the same HIV RNA parameters with use of ART. All other PY were considered UC. Progression out of EC or MC status occurred if ≥12 undetectable HIV RNA values over ≥12 months in the absence of antiretroviral therapy (ART). MC required the same HIV RNA parameters with use of ART. All other PY were considered UC. Progression out of EC or MC status occurred if ≥12 undetectable HIV RNA values over ≥12 months in the absence of antiretroviral therapy (ART).

**Methodology:** Data from 112 participants in ANRS 100 (n=26) and ANRS 112 (n=86) trials who received 18-month ART initiated in acute PHI and underwent a scheduled treatment interruption were pooled for analysis. Logistic regressions were used to identify factors associated with a plasma HIV-1 RNA (VL) level <1000 cp/mL 6 months after cessation of therapy (viral set point). Median (interquartile range) results are presented.

**Results:** Median age was 34 years (29-41); 13 (12%) were women. Before treatment initiation, CD4 T cell count was 425 cells/mm3 (299-607), VL and total cell associated HIV-1 DNA levels were 5.7 log10 cp/mL (5.0-5.9) and 3.5 log10 cp/106 PBMC (3.0-3.7), respectively and number of Western blot antibodies was 2 (1-3). At completion of 72-84 weeks of treatment, VL was <50 cp/mL in 83/108 (77%) patients, CD4 T cell count had increased to 682 cells/mm3 (556-852) and HIV DNA decreased to 2.3 log10 cp/106 PBMC (1.8-2.7).

Six months after ART interruption, median VL was 3.9 log10 cp/mL (3.0-4.3). VL was <1000 cp/mL in 26 patients (23%, 9/13 women and 17/99 men) and <50 cp/mL in 7 patients (6.2%, 4/13 women and 3/99 men, p=0.003 Fisher’s exact test). Female sex and a low baseline VL were significantly associated to a low viral set point; a high CD4 T cell count at baseline showed a trend. Patient’s age, trial number of Western-blot antibodies, CD8 T cell count at baseline, HIV DNA level at baseline and at treatment interruption were not associated with viral set point. In multivariate analysis, female sex was the only variable significantly associated to an increased likelihood of VL <1000 cp/mL (p=0.02). Considering men only (n=99), 17% achieved a VL <1000 cp/mL 6 months after interruption and no predictive factor of viral set point was identified among CD4 T cell count, VL or HIV DNA level at initiation or at 18 months of treatment.

**Conclusions:** Women were more likely to control viral replication than men. After adjustment on sex, no other pretreatment or end-of-therapy characteristic was identified in this population to predict a low or undetectable VL 6 months after cessation of ART. This difference between men and women deserves further investigation.
A greater percentage of EC admissions were for cardiovascular (23% for EC, 16% MC, 11% UC) and pulmonary causes (20%, 5%, 5%) and less were for non-AIDS defining infections (4%, 21%, 29%).

Conclusions: Elite control is associated with higher hospitalization rates than medical control of HIV infection. Underlying mechanisms need to be explored and studies are needed to investigate whether ART might reduce hospitalizations among elite controllers.

Figure. All-cause hospitalization rates among patients with CD4 >350 by HIV control status

557 CD4 Cell Count Monitoring Frequency Among HIV+ Persons in New York City (NYC), 2007-2011
Julie E. Myers1, 2, Qiang Xia1, Lucia V. Torian3, Mary K. Irvine1, Blayne H. Cutler1, Graham Harriman1, Kent A. Sepkowitz2, Colin W. Shepard3
1Bureau of HIV/AIDS Prevention and Control, New York City Department of Health and Mental Hygiene, Queens, NY, United States, 2Department of Medicine, Division of Infectious Diseases, Columbia University Medical Center, New York, NY, United States, 3Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, United States

Background: National guidelines advise CD4 testing every 6-12 months in clinically stable HIV+ patients with suppressed HIV viral load (VL), while some quality management protocols require CD4 monitoring every 6 mos. To determine whether some patients could be safely tested less often, we used NYC surveillance data to explore CD4 testing among stable patients in NYC, 2007-2011.

Methodology: We constructed a population-based, retrospective open cohort analysis of NYC HIV Surveillance Registry data. HIV+ patients aged ≥13 years with stable viral suppression (≥1 VL in the previous calendar year; all measurements <400 copies/mL) and stable immune status (≥1 CD4 in the prior calendar year; all measurements ≥200 cells/mm³) entered the cohort the following year beginning on January 1, 2007. Each subsequent year, patients who were eligible and not previously enrolled entered the cohort on January 1. Patients were followed through 2012, and censored at first VL≥400 copies/mL or the last CD4/VL. The primary outcome was the probability of maintaining CD4≥200 cells/mm³. A multivariate Cox model was used to identify factors associated with maintenance of CD4≥200 cells/mm³.

Results: During a median 2.5 (interquartile range: 1.2, 4.7) years of observation, 58,691 stable patients entered the cohort (168,769 person-years of observation). Mean annual number of CD4 measurements among stable patients was 2.8 (standard deviation: ±1.3) and varied little by year or characteristic. Two years after entering, 66.9%, 91.9% and 97.8% of those with initial CD4 200-349 cells/mm³, 350-499 cells/mm³, and ≥500 cells/mm³, respectively, maintained CD4≥200 cells/mm³. Compared to those with initial CD4≥500 cells/mm³, those with CD4 200-349 cells/mm³ (adjusted hazard ratio [AHR] = 13.6, 95% confidence interval [CI], 12.7, 14.6) and CD4 350-499 cells/mm³ (AHR = 3.3, 95%CI: 3.1, 3.6) were more likely to have a CD4<200 cells/mm³, controlling for sex, race, age, HIV risk group, and diagnosis year.

Conclusions: In a population-based cohort with well-controlled HIV, initial CD4 at cohort entry was an independent predictor of maintaining CD4≥200 cells/mm³; the probability of maintaining CD4≥200 cells/mm³ for at least 2 years was >90% among those with initial CD4≥350 cells/mm³. These findings suggest that limited CD4 monitoring in individual patients is appropriate, especially among those with CD4≥350 cells/mm³; as additional testing is unlikely to require clinical action. At the New York State Medicaid rate of US$64.93 for a CD4 test in 2013, NYC would save approximately US$1.3 million or US$3.0 million annually, if CD4 monitoring were limited to twice yearly or once yearly, respectively, for stable patients with CD4≥350 cells/mm³.

558 Value of Viremia Copy Years in Deciding Optimal Timing of ART Initiation in Adults With HIV
Ashley Olson1, Sarah Walker1, Amitabh Suthar1, Caroline Sabin1, Heiner Bucher1, Imma Jarrin2, Santiago Moreno2, Santiago Perez-Hoyos2, Kholoud Porter1, Deborah Ford1
1ARC CTU UCL, London, United Kingdom, 2World Health Organization, Geneva, Switzerland, 3University College, London, London, United Kingdom, 4University Hospital Basel, Basel, Switzerland, 5Instituto de Salud Carlos III, Madrid, Spain, 6Instituto Ramón y Cajal de Investigación Sanitaria, Madrid, Spain, 7Universidad Autónoma de Barcelona, Barcelona, Spain

Background: Time updated VL levels and CD4 counts are routinely used to monitor HIV positive adults but fail to capture cumulative HIV exposure. Viremia copy years (VCY) is such a measure and has been shown to be predictive of AIDS/death, although it is unclear of its use in deciding when to start ART. We aimed to assess the impact of initiating vs. deferring ART on risk of AIDS/death by levels of VCY both independent of and within two CD4 strata, <350 and ≥350 cells/mm³.
Methodology: Using CASCADE data on HIV seroconverters, we created a series of nested cohorts corresponding to consecutive months starting month 5 post seroconversion (SC) for individuals ≥16 years at SC after 1997, had ≥1 VL measured 4-12 months post SC, were ART naïve and AIDS free prior to end of baseline month. Time to AIDS/death was compared in those initiating vs. deferring ART in the baseline month using Cox models adjusted for time independent factors: country, sex, risk group, SC year; and time dependent factors prior to the baseline month: age, time since last VL, and current CD4, VCY and VL (excluding the first 4 months post SC) and mean number of previous CD4/VL measurements/year. Robust variance was used to adjust for individuals contributing ≥1 baseline visit. We repeated analyses using CD4 strata <500 and ≥500 cells/mm3.

Results: Of 6497 individuals contributing ≥1 baseline month, 3089 (48%) initiated ART and 293 (5%) acquired AIDS/died. Median (IQR) CD4 at ART initiation was 322 (249, 419) cells/mm3. Pooling CD4 strata, hazard ratios (HR) of AIDS/death associated with initiating vs. deferring ART reduced as VCY increased, suggesting a stronger benefit of ART in those with higher VCY. Trends by VCY were different when stratifying by CD4; in patients with CD4<350 cells/mm3, there was an overall reduction in the HR of AIDS/death in all VCY groups (all HR < 1) with no evidence that this benefit varied by VCY (p=0.78). At CD4 ≥ 350 there was a trend for increasing benefit of initiation with increasing VCY, with the largest benefit seen in the VCY ≥ 100,000 c/mL group (HR, 95% CI = 0.56, 0.35-0.90); no evidence of benefit if VCY was < 20,000 c/mL. Results were qualitatively similar for CD4 strata ≥ 500 cells/mm3.

Conclusions: Although we cannot rule out the possibility of unmeasured confounding, it appears that limiting the cumulative HIV burden to < 100,000 VCY in individuals with CD4 ≥ 350 cells/mm3 through ART reduces the hazard of clinical outcomes by 44%.

559 Expansion of ART and Progressive Declines in All-Cause Mortality in British Columbia, Canada
Christopher Cheung1, Erin Ding2, Julia Zhu3, Benita Yip4, Lilian Lourenco2, Rolando Barrios5, Julio Montaner1, 2, Robert S. Hogg2, 3, Viviane Lima1, 2, David M. Moore2, 3
1University of British Columbia, Vancouver, BC, Canada, 2BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 3Simon Fraser University, Burnaby, BC, Canada

Background: Expansion of ART programs in recent years has been promoted as a means to reducing the further spread of new HIV infections. We examined the effect of such an expansion in British Columbia (BC), Canada on all-cause and cause specific mortality among participants in the provincial HIV/AIDS Drug Treatment Program (DTP).

Methodology: We analyzed data from participants aged ≥18 in the BC DTP to measure two-year mortality and causes of death from January 1, 2001 to December 31, 2012. Deaths were identified through record linkages with the BC Vital Statistics Agency and we used ICD-10 codes for the underlying cause of death. We conducted tests of trend and compared DTP participant characteristics by dividing the study time into two-year time periods for the entire study period. We used Cox proportional hazard models to determine the risk of death for participants who had received ART for at least 3 months. Participants initiating ART in the final two-year period were excluded from the latter analysis.

Results: A total of 3933 new participants initiated ART and a total of 8221 received ART during the study period (Table). Overall mortality in the DTP declined from 526/4028 (6.4%) of DTP participants in 2001-2002 to 219/6258 (3.5%) in 2011-2012 (p=0.018 for test of trend). HIV-related deaths decreased (3.8% to 0.9% of DTP participants, p=0.022) and similar decreases were observed in deaths due to chronic liver disease, cardiovascular disease, and suicides (p=0.008, 0.022, and 0.002; respectively). There were no trends with respect to deaths from non-AIDS infections or cancers or respiratory causes. Multivariate models, adjusted for age, gender, history of injection drug-use and adherence to therapy demonstrated that the risk of mortality was independently associated with ART initiation in 2003 - 2004 (adjusted hazard ratio [AHR] 0.74; 95% CI 0.56 - 0.98); 2005 - 2006 (AHR = 0.58; 95% CI 0.42 - 0.80); 2007-2008 (AHR=0.49; 95% CI 0.34 - 0.71) and 2009-2010 (AHR = 0.42; 95% CI 0.25 - 0.72) in comparison to 2001 - 2002 (reference).

Conclusions: We observed decreases in overall mortality and reductions in HIV-related deaths among participants in the BC DTP over the study period. However, we also observed declines in cardiovascular, liver-related deaths and suicides. These changes parallel a secondary expansion of ART in BC which suggests broad clinical benefits to HIV treatment expansion beyond classically-defined HIV-related conditions.
560 Higher CD4 at ART Initiation Predicts Greater Long Term Likelihood of CD4 Normalization
Frank J. Palella1, Carl Armon2, Joan S. Chmiel3, John T. Brooks4, Rachel Debes2, Richard Novak5, Bienvenido Yangco6, Kathy Wood2, Marcus Durham7, Kate Buchacz8
1Infectious Diseases, Northwestern University Feinberg School of Medicine, Chicago, IL, United States, 2Cerner Corporation, Vienna, VA, United States, 3Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL, United States, 4Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States, 5Infectious Diseases, University of Illinois College of Medicine at Chicago, Chicago, IL, United States, 6Infectious Disease, Infectious Disease Specialists, Tampa, FL, United States, 7HIV Epidemiology Research Team, Centers for Disease Control and Prevention, Atlanta, GA, United States, 8Centers for Disease Control and Prevention, Atlanta, GA, United States

Background: Higher plasma CD4 cell counts per mm$^3$ at ART initiation (AI-CD4) improve long-term CD4 responses and survival. Recent data suggest attaining CD4 > 750 is a clinically significant threshold for AIDS-related illness reduction and immune "normalization". We evaluated the effect of AI-CD4 on chances of achieving CD4 > 750 and mortality risk.

Methodology: Among HIV Outpatient Study patients seen during 1996-2012 for three or more years after AI, we analyzed CD4 trajectories and mortality rates per 100 persons-years (MR) by AI-CD4, and the association of AI-CD4 with achieving CD4 > 750 using Kaplan-Meier methods and Cox proportional hazards models.

### Time to achieving CD4 > 750 cells/mm$^3$ by CD4 cell count strata at ART initiation. HIV Outpatient Study, 1996-2012 (n = 1327)

- Censored
- 5: CD4 ≥500
- 4: CD4 350-499
- 3: CD4 200-349
- 2: CD4 50-199
- 1: CD4 <50 cells/mm$^3$
**Results:** Of 1327 eligible patients followed a median of 7.9 years, > 85% received HAART ≥ 75% of follow-up time, and 64 died. Higher AI-CD4 was associated with increased median peak CD4 (p < 0.001 for trend; see Table). Maximal CD4 response and benefit appeared to plateau at eight years, but differences by AI-CD4 strata persisted (p < 0.001 for trend; see Figure). Lower crude MRs (p = 0.005 for trend) and higher CD4 closest to death (p = 0.013 for trend) were associated with higher AI-CD4. Increases in median CD4 for persons with AI-CD4 < 50 and 50-199 seemed to converge by eight years after AI (<50% achieved CD4 > 750) whereas patients with AI-CD4 > 350 normalized by eight years (> 80% of patients). In multivariable analyses, higher AI-CD4 was the only factor independently associated with achieving a CD4 > 750 during follow-up through last HOPS contact.

**Conclusions:** Progressively higher AI-CD4 predicted greater long-term CD4 gains, greater chances of achieving CD4 > 750 (“normalization”), increased crude survival rates, and higher CD4 at death. CD4 gains and chances of reaching CD4 >750 peaked at eight years after AI. Most persons with AI-CD4 >350 eventually achieved CD4 normalization while less than half of persons with AI-CD4s < 50 and 50-199 did. AI-CD4 ≥ 500 optimized the likelihood of CD4 normalization. These data confirm the hazards of delayed AI and support AI at CD4 ≥ 500.

### 561 Is CD4 Monitoring Needed Among Ugandan Clients Achieving Virologic Response To Treatment?

**Steven J. Reynolds**, Joseph Sempa, Agnes N. Kiragga, Kevin Neevel, Gertrude Nakiigozi, Larry Chang, Ronald M. Galkwango, Ronald Gray, Thomas C. Quinn

1Division of Intramural Research, NIAID/NIH, Kampala, Uganda, 2Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 3Infectious Diseases Institute, Kampala, Uganda, 4Clinical Research Directorate/CMRP, Leidos Biomedical Research, Inc (formerly SAIC-Frederick Inc.), Frederick, MD, United States, 5Rakai Health Sciences Program, Kalisizo, Uganda, 6Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, 7Division of Intramural Research, NIAID/NIH, Bethesda, MD, United States, 8School of Public Health, Makerere University College of Health Sciences, Kampala, Uganda

**Background:** Immunologic monitoring with CD4 counts every 6 months is commonly performed for individuals receiving antiretroviral therapy (ART). In the setting of immunologic and virologic response to ART (CD4≥200 cells/ul and HIV viral load (VL) <400 copies/ml), it is unclear whether ongoing CD4 monitoring is necessary. We investigated the proportion of clients who achieved a virologic and immunologic response who had a subsequent decline in CD4 (<200 cells/ul) despite virologic suppression.

**Methodology:** Clients receiving ART through the Rakai Health Sciences Program in Uganda between June 2004-May 2013 were eligible for this analysis. We evaluated clients who had achieved a CD4≥200 cells/ul and a VL<400 copies/ml and had at least 3 pairs of sequential CD4 and VL measurements occurring within 390 days (a sequence). A CD4 count decline was defined as a drop in CD4 count to <200cells/ul during a period of viral suppression. Survival analysis was used to estimate time to first CD4 sequence and CD4 decline. A Cox proportional hazards model was used to identify factors associated with a CD4 decline.

**Results:** A total of 1553 clients were included, 68% females, mean (sd) age of 35.5 years (8.3), median (IQR) baseline CD4 count 183 cells/ μl (106-224). A total of 1482 (95.4%) clients had at least one sequence of CD4/ VL measurements, while 71 (4.6%) had more than one sequence. On average, clients acquired a sequence after 8.3 months on ART (6.9-14.2). In a per-client analysis, 43 clients (2.8%) developed CD4 declines, the majority occurring among individuals whose initial CD4 was <300 cells/ul (table 1). Of the 43 clients who developed declines, 24 had an additional CD4 measurement and 20/24 acquired a sequence after 8.3 months on ART (6.9-14.2). In a per-client analysis, 43 clients (2.8%) developed CD4 declines, the majority occurring among those who did not achieve a virologic and immunologic response who had a subsequent decline in CD4 (<200 cells/ul) despite virologic suppression.

**Conclusions:** Clients who achieved a CD4 count ≥200 cells/ul and a VL <400 copies/ml on ART were unlikely to experience a CD4 count decline to <200 cells/ul and among those who did experience a decline, the majority were transient in nature. As access to VL monitoring expands in resource limited settings, decreasing the frequency of CD4 count monitoring among virally suppressed clients may reduce costs.

Results: DART STI patients had >100 cells/mm³ lower CD4 when restarting CT (Figure). Subsequently STI patients gained 48 (95% CI 43-54) cells/year, significantly faster than the 31 (25-36) in CT patients (p<0.001). Extrapolating forward, those randomized to STI would have similar CD4 to those on CT 4-5 years after restarting ART. 32% (1055/3316) adults had total 1955 UPTIs lasting ≥4 days, vs 23% (281/1206) children (p<0.001) with 536 UPTIs, with median total 17 days (7-49) off treatment in adults vs 13 (7-34) in children. In both adults and children most UPTIs occurred in the first year on ART (p<0.001). The most common reason for UPTIs was inability to attend clinic (61% adults, 50% children). Adverse events were a more common reason in adults (22%, 1% children) and patient/carer decision in children (17%, 5% adults). For every extra cumulative month off ART (STIs+UPTIs) in adults CD4 4 years after ART initiation was 6 cells/mm³ lower (95%CI 2-8, p<0.001); in children CD4% 3 years after ART initiation was 2% lower (1-3%, p=0.001). Having ever interrupted ART increased mortality risk in adults (HR=3.0 [95% CI 2.1-4.2] p<0.001) with similar non-significant trend in children (HR=2.6 [0.7-10.4] p=0.18). There was no evidence of independent effects of cumulative time off ART in adults (HR=1.1 per doubling [1.0-1.2] p=0.26) or children (1.6 [0.9-2.8] p=0.11).

Conclusions:
TIs lead to lower CD4 counts over the long-term even after returning to ART, highlighting the importance of avoiding ART interruption in programmes in resource limited settings.

563  Failure of Initial HAART in Caribbean, Central and South America

Background: Access to highly active antiretroviral therapy (HAART) is expanding in Latin America (LAC). The aim of this study was to identify factors associated with failure of initial HAART.

Methodology: Antiretroviral-naive adults who started their first HAART on or after January 1, 2000 at participating CCASANet sites were included. Cumulative incidence of virologic failure and major regimen change was estimated considering death as a competing event. Hazard ratios (HR) were computed using univariate and multivariable Cox models. Secondary models with major regimen change as the outcome included Haiti (excluded from the primary analysis due to lack of viral load [VL] data).

Results: 13,954 HAART initiators met inclusion criteria (867 from Argentina, 1817 from Brazil, 1075 from Chile, 6468 from Haiti, 917 from Honduras, 811 from Mexico, and 1999 from Peru). Median follow-up was 3.7 years (interquartile range [IQR] 1.8 to 5.9). Nearly 60% of patients were male; the median age at HAART initiation was 37 years (IQR 30 to 44); median CD4 count was 152 cells/mm³ (IQR 60 to 249), and median VLwas 5 log10 copies (IQR 4.5 to 5.4 log10); 39% with AIDS (ranging from 8% in Argentina to 58% in Mexico); median frequency of VL measurement was 3.1 per year; 26% of patients from Honduras did not have VL available; this proportion was less than 2% for the other sitesMost patients at all sites started an NNRTI-based regimen. The cumulative incidence of virologic failure was 9.5%, 18.8% and 27.2% at 1, 3 and 5 years after HAART initiation, respectively. Virologic failure was associated with younger age (adjusted hazard ratio [aHR]= 1.94 for 20 vs. 40 years; 95% CI 1.61-2.34; p<0.001); prior AIDS (aHR=1.31; 95% CI 1.16-1.47; p<0.001); HAART start in earlier calendar years (aHR 1.34 for 2002 vs. 2006; 95% CI 1.21-1.50; p<0.001); non-NNRTI-based regimen (PI-base regimen aHR=1.29; other regimen aHR=1.47; p<0.001).

Similarly, younger age and AIDS were both associated with a decreased risk of regimen change (aHR=0.80 for 2002 vs. 2006). Predictors of major regimen change were similar between Haití and the Latin American sites.
**564 The HIV Treatment Cascade: Is There More To the Story?**

Baligh R. Yehia1,2, Alisa J. Stephens1, Allison L. Agwu1, Stephen A. Berry4, Joshua P. Metlay3, Kelly A. Gebo2

1University of Pennsylvania, Philadelphia, PA, United States, 2Johns Hopkins University, Baltimore, MD, United States, 3Massachusetts General Hospital, Boston, MA, United States

**Background:** The HIV treatment cascade is an effective framework for improving the delivery of care to people living with HIV (PLWH). Steps in the cascade are calculated in a conditional manner, with the number of persons completing the prior step serving as the base population for the next step. However, this approach may underestimate use of ART and viral suppression by excluding persons not meeting standard definitions of retention in care.

**Methodology:** Using 2010-2012 data from 13 HIV Research Network clinics, we calculated the proportion of patients completing the final two steps of the cascade: (1) use of ART for ≥6 months in the calendar year, and (2) viral suppression (HIV RNA <400 copies/mL) at the last measure in the 2nd half (Jul-Dec) of the year among those on ART. Cascade steps were stratified by retention in care (≥2 primary HIV visits separated by ≥90 days in the year). Multivariable regression compared characteristics of patients retained vs. not retained among those who were (1) on ART and (2) on ART and virally suppressed, adjusting for age, sex, race, HIV risk factor, insurance, initial CD4 count, and calendar year.

**Results:** A total of 28,569 adults (≥18-years-old) contributed 58,088 person-years (PY) to the analysis. Overall, patients were retained in care in 84%, on ART in 80%, and virally suppressed in 59% of PY. Following the standard cascade, 84% were retained in care, 70% were retained and on ART, and 55% retained, on ART, and virally suppressed. Therefore, we identified 10% of PY where patients did not meet retention criteria, but were on ART; and 4% of PY where patients did not meet retention criteria, but were on ART and achieved viral suppression. (Figure) Among patients on ART, those with heterosexual and IDU risk (vs. MSM) and lower CD4 counts were less likely to be retained; whereas older patients, Hispanics (vs. whites), and persons with public insurance (vs. private) were more likely to be retained (p-value <0.05). Similar associations were observed for patients on ART and virally suppressed, except CD4 count was no longer significantly associated with retention.

**Conclusions:** Excluding patients not retained in care from the HIV treatment cascade underestimates the proportion on ART by 10% and the proportion with viral suppression by 4%. These patients may receive care at outside clinics or have excellent self-management skills; thus not meeting retention criteria. Better understanding of how PLWH use outpatient HIV services may improve how we assess and design HIV care delivery.

**565 Cumulative Viral Load Predicts All-Cause and AIDS-Related Mortality After Initiation of ART**

Michael J. Mugavero1, Andrew O. Westfall1, M. John Gill1, Michael Saag1, Sophie Abgrall1, Gerd Fätkenheuer1, Peter Reiss2, Suzanne M. Ingle3, Margaret T. May3, Jonathan A. C. Sterne4, on behalf of ART-CC

1Division of Infectious Diseases, Department of Medicine, University of Alabama at Birmingham, Birmingham, AL, United States, 2School of Public Health, Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL, United States, 3Division of Infectious Diseases, University of Calgary, Calgary, AB, Canada, 4INSERM, UMR_S 1136, Institut Pierre Louis d’Epidémiologie et de Santé Publique, Paris, France, 5AP-HP, Hôpital Avicenne, Service des Maladies Infectieuses et Tropicales, Bobigny, France, 6Department of Internal Medicine, University of Cologne, Cologne, Germany, 7Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, 8School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom

**Background:** The prognostic value of cross-sectional viral load (VL) measures for clinical events following ART initiation is well established but the best way to quantify their association with clinical events and death over time is unclear.

**Methodology:** Treatment-naïve patients starting ART between January 2000 and December 2009 in one of 17 cohorts participating in the ART Cohort Collaboration (ART-CC) were included. Time-updated viremia copy-years (VCY) following ART initiation ("baseline"). VCY estimates the cumulative plasma viral burden based on the area under the VL curve and was calculated daily for each patient. We assumed a lower limit of detection of 500 copies/ml: values <500 were set to 250 for calculation of VCY. Procedures for standardized coding of deaths were adapted from the CoDe protocol. We used Cox models to estimate associations (hazard ratio [HR], 95% CI) of baseline and time-updated viral load, and time-updated VCY, with all-cause,
AIDS-related, and non-AIDS-related mortality. All models were adjusted for baseline age, sex, transmission risk group and cohort, and time-updated CD4 count.

Results: Among 33563 patients (mean age 39 years, male 71%, mean baseline CD4 217 cells/μL), a mean 13 viral load measures were available during mean 3.2 years following ART initiation. 1341 patients died, including 503 AIDS-related deaths, 614 non-AIDS-related deaths, and 224 unclassifiable/unknown deaths. All viral load measures predicted all-cause mortality, but time-updated VCY remained strongly predictive when adjusted for the other viral load measures. Similar patterns, with stronger associations, were observed for AIDS-related mortality. Associations with non-AIDS mortality were modest, with little evidence that any of the three VL measures independently predicts non-AIDS mortality.

Conclusions: Cumulative plasma viral burden following ART initiation better predicts all-cause and AIDS-related mortality than most recent VL, independent of time-updated CD4 count. None of the VL measures considered was clearly associated with non-AIDS mortality.

**ART: Adherence and Retention**

**566 Measures of ART Adherence Associated With Virological Failure in Rakai, Uganda**

Anthony Ndyanabo1, Fred Makumbi2, Gertrude Nakigozi1, David Senwadda1, Steven J. Reynolds1, Larry Chang1, Mary Grabowski5, Maria Wawer1, Ronald Gray1, Xiangrong Kong2

1Rakai Health Sciences Program, Kalisizo, Uganda; 2Makerere University School of Public Health, Kampala, Uganda; 3Division of Intramural Research, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, United States; 4School of Medicine, Johns Hopkins University, Baltimore, MD, United States; 5Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD, United States

**Background:** Adherence is a major predictor of antiretroviral therapy failure; however, viral load monitoring, which is the gold standard for monitoring the efficacy of HIV treatment and measuring validity of adherence reports, is often not feasible in resource limited settings. Simple adherence measures are available in the ART program in Rakai, Uganda, including measures based on pharmacy refill (PR), appointments and pill count. We examined whether these measures were associated with the occurrence of first virological failure (VF).

**Methodology:** We analyzed ART adherence and virological failure in 2710 patients aged 15 years or older who initiated ART from 2004 to 2012 in Rakai, Uganda. Adherence was measured using pill counts, pharmacy-refills and appointment attendance based on visits scheduled at two weeks during the first 3 months, then once per month for the first year, and once every two months after the first year. Viral load assays were done at six month intervals. We defined adherent patients as individuals who had at least 95% of pill count, appointment attendance or Pharmacy refills during the 6 months prior to viral load (VL) monitoring. The primary outcome was the occurrence of first VF using WHO’s 2013 criterion ≥1000 copies/ml. Three types of adherence measures (AM) were considered, based on 1) Pill count: ((Dispensed-Returned pills)/ (Pills prescribed during the 6 months)) 100%; 2) Appointments: ((total appointments attended with no delay)/(total expected appointments over a 6 months interval)) 100%; and 3) Pharmacy refill: ((Dispensed medication)/(pills prescribed during the 6 months)) 100%. Multivariate proportional hazards Cox model adjusted for age at VL visit, baseline regimen, WHO stage, CD4, Year of initiating ART and ART experience, was used to examine whether each AM was associated with time from ART initiation to first VF.
**Poster Abstracts**

**Results:** The median follow-up time was 46.4 months; IQR 23.8-69.5 months. VF during follow-up was observed in 16% patients (n=426) and 6% (n=27) of these persons subsequently died. The hazard ratios (HR) adherent to non-adherent associated with VF were: pill count (HR: 0.50, 95%CI 0.38-0.67), appointments (0.46, 95%CI 0.37-0.58) and pharmacy-refill adherence (HR: 0.29, 95%CI 0.22-0.37). Younger age (15-29) was associated with a two-fold significant increase in VF. The CBV/EFV regimen combination and the later year of initiating ART were associated with a significant reduction in risk for VF.

**Conclusions:** All adherence measures were predictive of VF. Because monitoring appointments requires the least effort in clinical settings, it may be a preferred method of assessing adherence in resource-poor settings and early detection of VF.

**567 Measures of Retention in HIV Care Differ in Their Associations With Clinical HIV Outcomes**

Baligh R. Yehia1, Peter Rebeiro2, Keri Althoff2, Stephen Gange2, Hasina Samji3, Michael Horberg4, Sonia Napravnik5, Kelly Gebo2

1University of Pennsylvania, Philadelphia, PA, United States, 2Johns Hopkins University, Baltimore, MD, United States, 3British Columbia Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 4Kaiser Permanente Mid-Atlantic States, Rockville, MD, United States, 5University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

**Background:** Retaining HIV-infected persons in care is important to receiving antiretroviral therapy (ART) and suppressing viral load. Multiple measures of retention are currently in use with no clear gold standard. Identifying which measures are most closely associated with favorable clinical outcomes may inform how we monitor retention in HIV care.

**Methodology:** We conducted a serial cross-sectional analysis of 22,261 adults (≥18-years-old) in 14 NA-ACCORD clinical cohorts between 2006 and 2010. Patients contributed one year of data during their first full calendar year of observation (subsequent to their year of entry into the cohort). Four measures of retention were calculated for each patient in this year: (1) US Department of Health and Human Services (DHHS), ≥1 visit in each half (Jan-Jun and Jul-Dec); (2) Health Resources and Services Administration (HRSA), ≥2 visits separated by ≥90 days; (3) 6-month gap, ≥6 months between sequential visits, with retention defined as no gap; and (4) 3-month visit constancy, number of 3-month intervals with ≥1 visit. Outcomes were: (1) CD4 >200 cells/mm3 and (2) HIV RNA ≤200 copies/mL at the last measurement in the year. Poisson regression examined the association between retention measures and the outcomes, adjusting for age, sex, race, HIV risk factor, initial CD4 count, use of ART, and calendar year.

**Results:** Overall, 75% of patients met the DHHS measure, 89% the HRSA, 85% did not have a 6-month gap, and 63% had visits in 3-4 quarters of the year: 84% had CD4 >200 cells/mm3 and 54% had HIV RNA ≤200 copies/mL. Retention measures varied in their associations with the outcomes. (Figure) The DHHS measure was the only metric significantly associated with CD4 >200 cells/mm3 (adjusted prevalence ratio 1.09, 95% CI 1.05-1.13). All measures were significantly and positively associated with HIV RNA ≤200 copies/mL: DHHS (1.31, 1.25-1.37), HRSA (1.25, 1.16-1.34), 6-month gap (1.19, 1.12-1.27), and 3-month visit constancy (1.20, 1.12-1.29 for 2 quarters; 1.36, 1.27-1.45 for 3 quarters; 1.42, 1.33-1.52 for 4 quarters).

Comparisons across measures indicate that the DHHS measure was the strongest predictor of both CD4 >200 cells/mm3 and HIV RNA ≤200 copies/mL (p<0.05).

**Conclusions:** Even though prior studies have shown that retention measures are strongly correlated, we demonstrate that measures vary in their association with clinical outcomes early in the course of patients’ care. The DHHS indicator may be the most useful measure to monitor retention in HIV care.

**Figure.** Percent of HIV-Infected Patients with CD4 Count >200 cells/mm³ and HIV RNA ≤200 copies/ml by Retention Measure

---

Note: To facilitate comparison with other measures, retention in care for the 3-month visit constancy measure was defined as having visits in 3-4 quarters of the year.
Immune, Virologic and Adherence Measures as Time-Dependent Predictors of Loss To Follow-Up
Seema T. Meloni1, Charlotte Chang1, Doug Hoi Cheung1, Beth Chaplin1, Holly Rawizza1, Oluwatoyin Jolayemi3, Bolanle Banigbe3, Prosper Okonkwo3, Phyllis Kanki1
1Immunology & Infectious Diseases, Harvard School of Public Health, Boston, MA, United States; 2Brigham & Women’s Hospital, Boston, MA, United States; 3AIDS Prevention Initiative in Nigeria, Ltd./Gte., Abuja, Nigeria

Background: For programs supporting large numbers of patients on ART, loss to follow-up (LTFU) and inadequate adherence pose major obstacles in achieving successful outcomes. In preliminary analyses examining patterns and predictors of attrition, we found that baseline CD4+ cell counts, baseline viral loads and early adherence patterns were associated with overall LTFU. In this evaluation, we further characterized the association of CD4+ cell counts, viral loads (VL), and treatment gaps on LTFU in a time-dependent fashion.

Methodology: From 2004-2012, Harvard/APIN received PEPFAR funds (HRSA #U51HA02522) to support and develop a sustainable HIV prevention, care and treatment program across multiple clinical centers in Nigeria. All patient ART-related data were collected and stored electronically. LTFU was defined as ≥60 days since the last scheduled refill date. For the analyses on CD4 counts and VL, we examined LTFU in 6-month increments, evaluating the CD4+ cell counts and VL taken at the prior visit as a predictor of loss in a time-dependent fashion. For the evaluation on large early treatment no LTFU, the gap was defined as a contiguous ≥90 days between refill dates during the first 6 months of treatment (i.e., “+90 gap”). Logistic regression methods were used to evaluate the association between +90 gap and LTFU.

Results: Between 2004-February 2011, the Harvard/APIN PEPFAR program enrolled 64,372 previously ARVnaive ART patients. Of those, 35% were eventually LTFU. In evaluating the association of CD4+ cell counts and VL suppression rates in a prior visit for months 6, 12, 18, 24, 30, 36, 42, and 48, we found that CD4+ cell counts and VL at prior visits remained significant predictors of attrition (p<0.05; Figure 1). Additionally, patients with the +90 gap were more likely to become LTFU beyond 6 months than those that did not have the gap (p<0.05). Patients with the +90 gap were less likely to have VL suppression and had a lower CD4 count increase by month 12 versus those without the gap (p<0.05).

Conclusions: The majority of analyses on LTFU focus on baseline measures as predictors of attrition. In this evaluation, we were able to show that time-dependent CD4+ cell counts and viral loads are continuous predictors of loss at 6-month time points starting at ART initiation extending to month 48 and that early large gaps in treatment were associated with LTFU within the first year of ART initiation. These data highlight additional indicators that should trigger counseling to ensure low rates of attrition.

Virologic Suppression With Second-Line Therapy: Does the Initial Regimen Matter?
Kevin L. Ard1, Lei Hua2, Camlin Tierney2, Eric S. Daar1, Paul E. Sax1
1Brigham and Women’s Hospital, Boston, MA, United States; 2Harvard School of Public Health, Boston, MA, United States; 3Harbor-UCLA Medical Center, Los Angeles, CA, United States

Background: In those experiencing virologic failure (VF) on first-line antiretroviral therapy (ART), the impact of the initial drug regimen on the rate of subsequent virologic suppression (VS) is unknown.

Methodology: We describe the outcomes of second-line therapy in those experiencing VF in the AIDS Clinical Trials Group A5202 trial, a randomized study comparing tenofovir/emtricitabine or abacavir/lamivudine with either efavirenz or atazanavir and ritonavir in treatment-naïve individuals. Following VF, subjects underwent resistance testing and were managed according to standard-of-care at the study sites. Subjects’ first-line regimen was defined as that taken at VF and was categorized as containing either a non-nucleoside reverse transcriptase inhibitor (NNRTI) or a ritonavir-boosted protease inhibitor (PI/rt). Subjects were classified as not taking ART at VF if they had not been on therapy for ≥ 8 weeks at the time of VF. VS on second-line ART was defined.
as an HIV RNA < 200 copies/mL at 24 weeks following confirmed VF. We compared VS between those who failed NNRTI- versus PI/r-based therapy using a Fisher’s exact test and a logistic regression model adjusting for age, sex, and HIV RNA, CD4 count, and resistance at VF, limiting the analysis to subjects with complete follow-up data.

Results: Of 1,857 subjects, 269 (14.5%) experienced VF; 94 (34.9%) and 134 (49.8%) failed their NNRTI- or PI/r-based first-line regimens, respectively, and 41 (15.2%) were not taking antiretrovirals at VF. Of subjects with genotype data at VF, resistance was detected in 71 of 92 (77.2%) failing NNRTI, 21 of 133 (15.8%) failing PI/r, and 17 of 41 (41.5%) not on ART. Therapy modifications following VF are shown in the table. At 24 weeks after confirmed VF, 141 of 155 (91.0%) subjects who had failed first-line NNRTI or PI/r therapy remained in the study on ART and had HIV RNA values available. VS was achieved on second-line ART in 42 of 56 (75.0%) subjects failing NNRTI and in 55 of 85 (64.7%) failing PI/r (unadjusted P=0.265, adjusted P=0.602); in a missing=failure sensitivity analysis, 44.7% failing NNRTI and 41.0% failing PI/r achieved VS (unadjusted P=0.590, adjusted P=0.741).

Conclusions: Among those with follow-up data, therapy was changed more often following failure of NNRTI- versus PI/r-based first-line regimens, likely due to increased resistance. However, subsequent virologic suppression on second-line ART at 24 weeks did not differ significantly between the initial drug regimens.

Conclusion: Among those with follow-up data, therapy was changed more often following failure of NNRTI- versus PI/r-based first-line regimens, likely due to increased resistance. However, subsequent virologic suppression on second-line ART at 24 weeks did not differ significantly between the initial drug regimens.

570 Favorable Long-Term Outcomes of 2nd-Line ART Despite Drug-Resistant HIV-1 in Sub-Saharan Africa

Tamara S. Boender¹, Kim G. E. Sigaloff², Raph L. Hamers³, Cissy Kityo⁴, Margaret Swale⁵, Mariette E. Botes⁶, Kishor Mandalaya⁷, Maureen Wellington⁸, Suleiman Akanmu⁹, Tobias F. Rinke de Wit¹⁰

¹Department of Global Health, Amsterdam Institute for Global Health and Development, Amsterdam, Netherlands, ²Department of Global Health, Department of Internal Medicine, Amsterdam Institute for Global Health and Development, Amsterdam, Netherlands, ³Joint Clinical Research Centre, Kampala, Uganda, ⁴Lusaka Trust Hospital, Lusaka, Zambia, ⁵Muelmed Hospital, Pretoria, South Africa, ⁶Coast Province General Hospital, Mombasa, Kenya, ⁷Newlands Clinic, Harare, Zimbabwe, ⁸Lagos University Teaching Hospital, Lagos, Nigeria

Background: With the expansion of antiretroviral therapy (ART) in resource-limited settings, the number of people with treatment failure and need for 2nd-line regimens will increase. We assessed the long-term effectiveness of boosted protease inhibitor (bPI)-based 2nd-line ART in 13 African settings, in patients with and without extensive nucleoside reverse transcriptase inhibitor (NRTI) resistance mutations at the time of regimen switch. Additionally, we explored the accumulation of protease resistance mutations.

Methodology: In an observational cohort, HIV-RNA and genotypic resistance testing was performed in adults who switched to bPI-based 2nd-line regimens at 13 clinical sites in Kenya, Nigeria, South Africa, Uganda, Zambia and Zimbabwe. Genotypic sensitivity score (GSS) was calculated using the Stanford algorithm. Associations between mutations present at the time of switch and virological failure (VF) after 12 or 24 months of ART were assessed using chi-square tests.

Results: Of 243 patients who started 2nd-line ART, 54% harbored drug resistant HIV with a GSS < 3, leading to a partially active 2nd-line regimen. After 12 and 24 months, 88% and 79% of patients were retained in care, respectively (Figure). After 12 months, 29 out of 206 (14%) patients with available viral load (VL) had VF, compared to 27 out of 177 (15%) after 24 months (p=0.745). Of 29 patients with VF at 12 months, 10 (35%) also had VF at 24 months, and 10 (35%) were re-suppressed, and the remainder was lost to follow-up, died or switched to 3rd-line ART. A partially active 2nd-line regimen at the time of switch...
was not significantly associated with VF at 12 or 24 months of follow-up (p = 0.586 and p = 0.897, respectively). At 12 and 24 months, 53% and 75% of patients with genotypic test results harbored drug resistant HIV, respectively. Protease mutations were present in 1 (6%) and 6 (30%, p = 0.097) sequences at 12 and 24 months. Protease mutations were M46I (n = 5), V82A (n = 4) and I84V (n = 1), and occurred in combination with NRTI mutations 5 out of 6 times (p = 0.095). A partially active regimen at the time of switch was not significantly associated with protease resistance development (p = 0.354).

Conclusions: Favorable virological response to 2nd-line bPI-based ART was maintained over 2 years, despite extensive NRTI resistance at the time of switch. While still infrequent by month 24, increasing protease resistance over time may become a barrier to successful long-term bPI-based ART in resource-limited settings.

571 Predictors of Time To Switch To Second Line ART After First Line Failure in Johannesburg South Africa
Julia K. Rohr, Prudence Iwe, Rebecca Berhanu, Kate Shearer, Mhairi Maskew, Lawrence Long, Ian Sanne, Matthew P. Fox

Background: Many patients with documented virologic treatment failure on first line antiretroviral therapy (ART) need to be switched to a second line regimen. In South Africa, national treatment guidelines state that patients with two consecutive failing viral load measurements on non-nucleoside reverse transcriptase inhibitor first line treatment should be switched to a protease inhibitor based regimen. Yet, there are often long delays in switching if it occurs at all. To better understand why delays occur, we explored whether clinic attendance or disease progression was more likely to explain delays in second line initiation.

Methodology: We conducted an observational cohort study using data from Themba Lethu Clinic in Johannesburg, South Africa, a large, public sector HIV clinic. We included all adult patients initiating first line ART since April 2004 with virologic failure (date of 2nd consecutive viral load ≥ 1,000 copies/mL) at least 1 year before the end of the study period in 2013. We looked for demographic, clinical, and visit adherence predictors of time to switch to second line ART after first line failure using Cox proportional hazards regression to adjust for confounders.

Results: 16825 patients initiated first line ART, of which 1578 (9.4%) failed after a median (IQR) of 22.8 (13.7-38.6) months. Of the 1578 who failed 60% were female. At time of failure, mean (SD) age was 39.2 (9.1) years, mean (SD) CD4 count was 244 (183) cells/mm³, and median (IQR) viral load was 8700 (2728-41000) copies/mL. 69% (1086) of failing patients switched to second line ART in a median (IQR) of 2.8 (1.0-6.6) months. A faster rate of switching was seen in
patients with higher viral load, lower CD4 count and shorter duration on first line ART prior to failure (Table). We found some evidence that differences in clinic attendance after failure explained how quickly switches occurred; a smaller proportion of patients who switched by 6 months had missed visits in the first 6 months after failure (31%) than those who did not switch by 6 months (45%).

Conclusions: We found that disease severity at first line failure predicted faster switching, with patients with higher viral load levels and lower CD4 counts being switched to second line more quickly. Lack of visit adherence before failure had a minimal effect on delaying second line ART, and the majority of patients did not miss visits within the 6 months following failure, indicating delay in second line ART initiation is not solely explained by patients missing visits.

Background: Dolutegravir (DTG) is a second generation integrase inhibitors ( INSTI ), active in patients harboring first-generation INSTI resistant virus. In France, DTG is currently available in early access program (EAP) in salvage therapy. DTG has shown in vitro activity on HIV-2 isolates. We report preliminary safety and efficacy data of DTG containing regimens in HIV-2 infected patients with virological failure.

Methodology: Data from all HIV-2 infected patients with virological failure to raltegravir, receiving DTG 50 mg bid with optimized background antiretroviral (OB ARV) regimens were included in EAP. Plasma HIV-2 RNA (pVL) was performed at time of DTG initiation (baseline), Month 3 (M3) and M6. Cumulative genotypic resistance tests (current and historical) were interpreted according to the last version of ANRS algorithm (v23). ARV plasma concentrations (C12h) were determined using LC-MS/MS. Demographic, biological and therapeutic characteristics were recorded. Medians (IQR) were presented.

Results: A total of 13 HIV-2 infected patients (sex ratio M/F 11:2) aged 51 years, with 15 years infection duration and having received 16 previous ARV prescriptions had been included in EAP. Median follow up was 9 months (min: 3 - max: 15). HIV-2 groups were: A (n=9), B (n=3) and H (n=1). HIV-2 tropism was RS in 3 patients. Baseline median pVL and CD4 cells count values were 4548 cp/mL (885-21,199) and 97 cells/mm3 (62-157), respectively. Available integrase genotypic resistance patterns were: Y143R (n=6), Y148R/S (n=2), N155H (n=3). OB ARV conferring GSS below or equal to 2 in 10 patients, included: DRV/r (n=12), SQV/r (n=2), MVC (n=3) associated with NRTIs. Among them, 5 patients received in addition foscamet induction treatment (4 of whom with ZDV). At M3 and M6 pVL was undetectable in 6/10 and 4/8 patients respectively, and median CD4 cells count was 165 (76-165) and 167 (118-159). DTG C12h was 4457ng/mL (2453-5790) in 9 patients. One patient died from progressive multifocal leukoencephalopathy at M4. No other serious clinical or biological events led to DTG discontinuation.

Conclusions: These preliminary results demonstrated that DTG containing regimens provide a substantial efficacy rate for salvage therapy in heavily ARV experienced HIV-2 infected patients with virus harboring resistance to first-generation INSTI. Larger patients numbers and longer follow up are needed to confirm these findings.

573 Long Term Outcomes of ART in HIV-2 Infection in Senegal, West Africa
Selly Ba1, Robert A. Smith2, Dana N. Raugi2, Macoumba Toure3, Alassane Niang3, Ibrahima Sall3, Ousseynou Cisse3, Moussa Seydi1, Papa Saif Sow1, Geoffrey S. Gottlieb2, University of Washington–Dakar HIV-2 Study Group
1Clinique des Maladies Infectieuses Ibrahima Diop Mar, Centre Hospitalier Universitaire de Fann, Université Cheikh Anta Diop de Dakar, Dakar, Senegal, 2Medicine, University of Washington, Seattle, WA, United States, 3Région Médicale de Ziguinchor, Ziguinchor, Senegal

Background: Long-term outcomes of antiretroviral therapy (ART) for HIV-2 infection have not been reported. Emerging data suggest that ART for HIV-2 infection may be complicated by high rates of clinical and virologic failure, poor immune reconstitution and multi-class ARV-resistance.

Methodology: A cohort study of ART for HIV-2 infection in Dakar was initiated in 2005 and in Ziguinchor, Senegal in 2010. ART was provided by the Initiative Sénégalaise d’Accès aux Antirétroviraux. Patients were treated with 2 NRTIs and a protease inhibitor (PI), and Aluvia (lopinavir/ritonavir)-based ART became available in 2009. Patients were monitored every four months for clinical and immuno-virologic outcomes as well as adverse events. Time to virologic failure, genotypic ARV-resistance, CD4 count changes, adverse events, all cause mortality and loss to follow-up were analyzed.

Results: 165 patients were enrolled (females 68.5%; median age 49 years) between 2005-2013 with a median time of follow-up of 1.53 years (IQR: 0.52-3.76). All cause mortality was 10.8% with a median time to death of 1.00 years (IQR: 0.20-2.64). Lost to follow-up (LTFU; no contact > 1 year) was 22.4% with a median time to LTFU of 1.09 years (IQR: 0.46-2.42). 57.4%, 47.5%, and 34.9% of subjects had undetectable HIV-2 plasma viral loads at 1, 3 and 5 years respectively. Median CD4 counts increased from baseline (190 cells/mm3) to 277, 293, and 385 cells/mm3 at 1, 3 and 5 years, respectively. Fifteen new WHO stage 3 or 4 AIDS-associated clinical events were reported within the first year after initiation of ART, and 34 new events were reported during subsequent follow-up. Tuberculosis (n=19) and chronic diarrhea (n=23) were common. Of the 44 ARV-treated patients for whom
genotypic resistance data were available, 34% showed evidence of multi-class (NRTI and PI) drug resistance and an additional 34% showed evidence of NRTI resistance.

**Conclusions:** Long term outcomes of HIV-2-infected patients on ART in Senegal, West Africa are suboptimal with high rates of death, loss to follow up, AIDS-associated clinical events, immuno-virologic failure and ARV-resistance. Further studies comparing PI-based and integrase inhibitor-based regimens are needed, preferably in the setting of randomized clinical trials.

### 574 Raltegravir-Associated Mutations in HIV-2 Confer Cross-Resistance To Dolutegravir In Vitro

**Robert A. Smith**, Dana Raugi, Charlotte Pan, Sali Sow, Moussa Seydi, James Mullins, Geoffrey Gottlieb, the University of Washington-Dakar HIV-2 Study Group

*Allergy and Infectious Diseases, University of Washington, Seattle, WA, United States; Bill and Melinda Gates Foundation, Seattle, WA, United States; Allergy and Infectious Diseases, Clinique des Maladies Infectieuses Ibrahim DIOP Mac Dakar, Senegal; Microbiology, Medicine and Laboratory Medicine, University of Washington, Seattle, WA, United States*

**Background:** Raltegravir (S/GSK1349572) recently became the third integrase strand transfer inhibitor (INSTI) approved for antiretroviral therapy of HIV-1. Although raltegravir and other INSTI might also be useful for treating HIV-2 infection, the clinical efficacy of raltegravir has not been evaluated in HIV-2 patients, and data assessing the activity of the drug against HIV-2 in culture are scarce.

**Methodology:** HIV-2 isolates from antiretroviral-naive individuals were tested for susceptibility to dolutegravir using a single-cycle indicator cell assay. Amino acid changes associated with INSTI resistance were engineered into a molecular clone of HIV-2 via site-directed mutagenesis, and the dolutegravir sensitivities of the resulting variants were determined in single-cycle and multi-cycle assays.

**Results:** Dolutegravir inhibited group A and B strains of HIV-2 with mean EC50 values comparable to that observed for wild-type HIV-1 isolates (2.0 ± 0.7, 2.8 ± 0.3, and 1.1 ± 0.2 nM, for HIV-2/A, HIV-2/B, and HIV-1, respectively). HIV-2 integrase substitutions E92Q, Y143C, Q148K and Q148R conferred 2-9-fold resistance to dolutegravir, and the combinations E92Q+Y143C, E92Q+N155H, T97A+N155H, G140S+Q148R and T97A+Y143C resulted in 6- to >5000-fold resistance to the drug. Altogether, 9 of the 13 HIV-2 mutants tested were resistant to dolutegravir in culture.

**Conclusions:** Unlike HIV-1, mutations in all three of the principal pathways involved in raltegravir and elvitegravir resistance confer cross-resistance to dolutegravir in HIV-2. Thus, three mutational pathways in HIV-2 lead to class-wide integrase inhibitor resistance. These findings suggest that dolutegravir-containing regimens may not be effective in HIV-2 patients that have developed resistance to other INSTI.

### 575 Predicting the Extinction of HIV-2 in Guinea-Bissau

**Helen Fryer**, Carla van Tienen, Maarten Schim van der Loeff, Matthew Cotten, Hilton Whittle, Peter Aaby, Sarah Rowland-Jones, Thushan de Silva, Hilton Whittle, Peter Aaby, Sarah Rowland-Jones

*Department of Zoology, Oxford University, Oxford, United Kingdom; Medical Microbiology & Infectious Diseases, Erasmus Medical Centre, Rotterdam, Netherlands; Medical Research Council Laboratories (UK), Fajara, Gambia; Health Service of Amsterdam (GGD) and Academic Medical Centre, Amsterdam, Netherlands; Internal Medicine, Academic Medical Center, Amsterdam, Netherlands; Wellcome Trust Sanger Institute, Hinxton, United Kingdom; London School of Hygiene and Tropical Medicine, London, United Kingdom; Medical Research Council (UK), Fajara, Gambia; Bandim Health Project, Bissau, Guinea-Bissau; Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom; Department of Infection and Tropical Medicine, Royal Hallamshire Hospital, Sheffield, United Kingdom*

**Background:** HIV-2 is less virulent than HIV-1 but can cause AIDS indistinguishable from AIDS caused by HIV-1. Guinea-Bissau is believed to be the nucleus of the HIV-2 epidemic and the prevalence was >20% in the 1980s in elderly in Caio, a rural area. In 1990-2007, HIV-2 prevalence halved and in 2007 infection amongst young adults in the region was very low (<1% in 15-34 year olds). However, HIV-2 prevalence was still 12% amongst individuals aged ≥45, due in part to increased susceptibility of women to HIV-2 with increasing age. This suggests that HIV-2 may persist as an infection of the elderly. Through a model we aimed to answer the following questions: will HIV-2 in Caio go extinct and if so, when would this happen, or will it persist as an infection among elderly?

**Methodology:** A deterministic transmission model was developed and fit to the age-stratified incidence and prevalence data from the HIV-2 epidemic in Caio, as measured in 3 serosurveys in 1990, 1997 and 2007. In the model the population is segregated into 3 states: Susceptible, Infected and Removed (SIR model). A stochastic version of the model was also formulated by allowing death and infection to be governed by probabilistic methods and this version was used with 1000 simulations to make future predictions of HIV-2 prevalence and incidence.
Results: Our model predicts that HIV-2 infections (including dual HIV-1/2 infections) will continue to decline in prevalence and become extinct in Caió this century. HIV-2 prevalence is expected to fall below 0.1% by 2053 (95% CI: 2043-2074) (Figure 1A). New infections are predicted to cease around 2047 (2029-2083) (Figure 1B) but complete extinction is expected to take longer. Mortality rates are relatively low for HIV-2, as compared to HIV-1, meaning that the last few individuals will acquire infection may survive for decades. Extinction is expected to occur around 2071 (2054-2106).

Conclusions: Based on our model, it is predicted that HIV-2 infection will continue to decline rapidly in Caió such that new infections will cease and prevalence will reach low levels. HIV-2 will go extinct in Caió during the second half of this century. HIV-2 epidemics in other parts of the world have behaved in a very similar way thus far, making global extinction of HIV-2 a possibility. As low plasma viral loads play a key role in the restricted transmission and therefore decline of HIV-2, we highlight the relevance of our results to the potential control of the HIV-1 epidemic via universal treatment.

576 HIV-2 X4 Tropism Is Associated With Lower CD4 Cell Count in Treatment-Experienced Patients

Benoit Vissieux1,2, Charlotte Charpentier1,2, Caroline Rouard1, Catherine Fagard1, David Glohi3, Roland Tubiana3, Florence Damboudji, Françoise Brun-Vézinet1,2, Sophie Matherton1, Diane Descamps1,2, the French HIV-2 ANRS Cohort C05

1Laboratoire de Virologie, Hôpital Bichat Claude Bernard, Paris, France, 2IAME UMR 1137 INSERM and Paris Diderot University, Paris, France, 3Université Bordeaux 2, INSERM, Bordeaux, France, 4Maladies Infectieuses et Tropicales, Hôpital Bichat Claude Bernard, Paris, France, 5Maladies Infectieuses et Tropicales, Hôpital de la Pitié-Salpêtrière, Paris, France

Background: Genotypic tools for HIV-2 tropism determination have been recently established. In vitro studies have demonstrated that maraviroc has efficacy against HIV-2. Currently, maraviroc use is only considered in highly pre-treated HIV-2 patients. However, R5/X4 tropism distribution is still unknown during HIV-2 infection. The aim of this study was to describe HIV-2 tropism distribution in treatment-experienced patients and to compare CD4 cell count and number of drug resistances mutations in R5 and X4 viruses.

Methodology: All samples received for HIV-2 tropism in routine testing between April 2009 and June 2013 issued from ART treated patients experiencing virological failure were included. At time of tropism determination, CD4 cell count, HIV-2 viral load and genotypic resistance testing (protease, RT, integrase) results were collected. Genotypic resistance tests were interpreted according to the new European resistance algorithm (http://www.genov2pheno.org/). Associations between tropism and variables were tested by Mann-Whitney or Fisher exact tests.

Results: 83 patients were included (47 Group A, 33 Group B, 3 not available). Among them, CD4 cell counts, HIV-2 viral load, and genotypic resistance results were available in 67 samples (81%), 75 (90%) and 77 (93%), respectively. 35 (42%) viruses were predicted as R5 and 48 (58%) as X4; with no significant difference between groups A and B (p = 0.65). Median CD4 cell counts were 220 ([Q1 = 155-395] and 88 cells/mm3 ([Q1 = 52-171]) in R5 and X4 groups, respectively (p < 0.0001). Tropism distribution among CD4 cell counts strata is depicted in the table below.

<table>
<thead>
<tr>
<th>CD4 cell count (mm3)</th>
<th>0-50</th>
<th>51-100</th>
<th>101-200</th>
<th>201-350</th>
<th>&gt;350</th>
</tr>
</thead>
<tbody>
<tr>
<td>% R5 (n)</td>
<td>17 (2)</td>
<td>7 (1)</td>
<td>41 (7)</td>
<td>75 (9)</td>
<td>64 (7)</td>
</tr>
<tr>
<td>% X4 (n)</td>
<td>83 (10)</td>
<td>93 (14)</td>
<td>59 (10)</td>
<td>25 (3)</td>
<td>36 (4)</td>
</tr>
</tbody>
</table>

Conclusions: A high proportion of X4 viruses was observed (58%), particularly in patients with CD4 cell count below 100/mm3. Patients with X4 viruses had lower CD4 cell counts and a higher number of drug resistance mutations, suggesting a longer treatment history. Thus, as in HIV-1, maraviroc use in HIV-2 salvage therapy may be compromised by a high proportion of X4 viruses. These results suggest that maraviroc use must be evaluated earlier in the infection in order to optimize the HIV-2 limited therapeutic arsenal.

Primary HIV Drug Resistance

577 Current First-Line Regimens Are Effective in Patients With Single Transmitted TAM

Claire M. F. Van Nispen tot Pannerden1, Abdellah El Barzouhi2, Ard I. van Sighem1, Jan M. Prins3, Suzanne Jurriaans3, Nicole K. Back4, Kees Brinkman2, Martijn E. Van der Ende2, Martin Schutter2

1Medical Microbiology and Infectious Diseases, Erasmus Medical Center, Rotterdam, Netherlands, 2Erasmus Medical Center, Rotterdam, Netherlands, 3Department of Infectious Medicine, Division of Infectious Diseases, Amsterdam Medical Center, Amsterdam, Netherlands, 4Department of Virology, Academic Medical Center, Amsterdam, Netherlands, 5Department of Internal Medicine, Onze Lieve Vrouwe Gasthuis, Amsterdam, Netherlands

Background: Thymidine Analogue Mutations (TAMs) are currently the most prevalent transmitted resistance-associated mutations in Western European countries. Maraviroc has been shown to be an effective combination antiretroviral therapy (cART) regimen with a low barrier to resistance development (GBR) (two NRTI and one NNRTI). This study analyzes the effect of transmitted single TAMs on efficacy of these regimens.

Methodology: Treatment-naive Men who have Sex with Men (MSM) diagnosed with HIV between 2002 and 2012 were selected from the ATHENA national observational HIV cohort in the Netherlands. Patients were classified into three groups: (1) a single resistance-associated mutation on a TAM position (‘TAM group’), (2) a single resistance mutation on a non-TAM position or ≥2 resistance mutations (‘RAM group’), and (3) no resistance or only non-wildtype mutations (‘WT/non-WT’). Virological failure (VF) was defined as the first of <1 log10 decrease in HIV RNA 4-8 weeks after start of cART, 200 copies/mL.
after 16 weeks. Time to VF was analyzed using proportional hazards models. Patients were censored at the date of treatment interruption, the date of the last available RNA measurement, or 64 weeks after starting cART, whichever was earliest. Active regimen was defined as a Genetic Susceptibility Score (GSS) ≥3.

**Results:** Of the 2314 diagnosed MSM, 104 (4%) were in the TAM group (97 full active regimen), 126 in the RAM group (75 fully active regimen). In total, 249 (11%) patients experienced VF. Compared to patients in the WT/non-WT group, time to VF was not different for the TAM group (relative hazard [RH] 1.04 (95% CI 0.58-1.86, p=0.9) or for RAM with a fully active regimen (RH 0.60, 0.25-1.47), but was shorter in RAM with a non-fully active CART regimen (GSS <3) (RH 2.19, 1.19-4.03). In 1537 (66%) patients starting on 1 NNRTI + 2 NRTI, RH for VF was 1.26 (95% CI 0.59-2.70, p=0.5) in the TAM group, 0.61 (0.15-2.47; p=0.5) in the RAM group with fully active cART, and 2.82 (1.32-6.08; p=0.008) in the RAM group with non-fully active CART compared to WT/non-WT. No differences were observed for patients starting high GBR regimens. Pretreatment viral load <100000 c/mL was associated with lower hazard of VF compared to ≥100000 c/mL (RH 0.52, 95% CI 0.40-0.69, p=0.001).

**Conclusions:** The presence of a transmitted single TAM does not affect the efficacy of currently used first-line cART regimens.

578 **Drug Resistance Mutations in Treatment-Naive HIV-Infected Patients 2000-2013**
Nicolas A. Margot, Ross Martin, Michael D. Miller, Christian Callebaut
Clinical Virology, Gilead Sciences Inc., Foster City, CA, United States

**Background:** HIV integrase (IN) has become an important target for HIV antiretroviral (ARV) therapy with the introduction of IN strand transfer inhibitors (INSTIs), such as raltegravir (RAL), elvitegravir (EVG), and dolutegravir (DTG). Presence of pre-existing mutations in IN may affect the efficacy of this class of ARVs. Here we report the results of a retrospective genotypic analysis of a large dataset of ARV-naive subjects from Phase 3 clinical samples over a 13 years period.

**Methodology:** Plasma samples from 4 Phase 3 studies in ARV-naive HIV-1 infected patients were collected at screening before any drug treatment. The plasma HIV-1 was population sequenced at IN, RT and PR and compared to the HIV-1 reference sequence NL4-3. The number of amino acid changes from reference was tabulated and compared across the studies, and statistical analyses performed. Characteristics such as presence of resistance-associated-mutations (RAMs), subtype, and enrollment year were analyzed.

**Results:** Sequences from clinical studies GS-99-903 (RT, n=598; IN, n=100), GS-01-934 (RT, n=501; IN, n=100), and GS-US-292-0104/0111 (RT/IN, n=1471), enrolled in 2000, 2003, and 2013, respectively, were included in the dataset (RT, n=2516; IN, n=1617). The clinical studies were enrolled mostly in the U.S. and Western Europe with predominantly subtype B HIV-1 (n=2317). From 2000/2003 to 2013, the presence of NRTI hallmark transmitted drug resistance (TDR) mutations (K103N/S, Y181C/I/V, and/or G190S/A in RT) increased from 1.9% to 7.8%. NRTI TDR remained low, with TAMS decreasing slightly from 2.7% to 2.2% and the mutations K65R and M184V/I remaining below 0.1% through 2013. The frequency of primary INSTI RAMs (T66A/I/K, E92G/Q, G140S, Y143C/H/R, S147G, Q148H/K/R, N155H/S) remained extremely rare with only one instance of T66I/T mixture with wild-type observed in the 2013 dataset (0.07%). Additionally, the polymorphic T97A IN substitution, which has been associated with minor INSTI resistance, was present at low levels (1.2%) but not found along with other INSTI RAMs. Interestingly, during the same time period, the overall number of IN substitutions vs. reference among the subtype B sequences increased from an average of 11.4 to 12.9 substitutions per patient (p <0.0001) suggesting possible evolution within IN over time.

**Conclusions:** This analysis showed that through 2013, primary HIV-1 integrase resistance mutations were very rare (1/1617 samples) in treatment-naive patients. Resistance to NRTIs also remained low, while primary NRTI resistance was observed in >8% of treatment-naive patients. These results suggest that transmitted drug resistance is unlikely to affect treatment with most INSTI-containing regimens.

M. Cheryl Bahez Ocefmia, Neeraja Saduvala1, Alexandra M. Oster1, David Kim1, Richard Kline1, Magan Pearson1, Angela L. Hernandez1, H. Irene Hall1
1National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States, 2ICF International, Atlanta, GA, United States

**Background:** Men who have sex with men (MSM) bear the heaviest burden of HIV in the United States. Effective antiretroviral therapy (ART) is crucial for viral suppression and reduced transmission. We used National HIV Surveillance System data to assess the prevalence of transmitted drug resistance among MSM.

**Methodology:** We analyzed HIV-1 pol sequences from persons newly diagnosed with HIV during 2008-2011 in 11 U.S. jurisdictions and who had no evidence of ART use. We used the CDC HIV-1 surveillance mutation list to identify transmitted drug resistance-associated mutations (TDRM) for non-nucleoside reverse transcriptase inhibitors (NNRTI), nucleoside reverse transcriptase inhibitors (NRTI), and protease inhibitors (PI). For MSM, we compared TDRM prevalence by age, race/ethnicity, large city of residence (Chicago, Dallas, Denver, Detroit, Los Angeles, Miami, New Orleans, New York City, Seattle), and duration of infection, determined using BED HIV-1 Capture EIA results. Absent a BED result, infections with a negative HIV test ≤ 6 months before HIV diagnosis were classified as recent. Infections with AIDS ≤ 6 months after HIV diagnosis were classified as long-standing (LS). To compare TDRM prevalence between groups, we calculated prevalence ratios (PR) and 95% confidence intervals (CI).

**Results:** Of all 16,985 diagnosed infections, 2,836 (16.7%) had any TDRM, compared to 1,894 (17.4%) of 10,894 infections among MSM. TDRM prevalence among MSM was 9.0% for NNRTI, 6.6% for NRTI, and 4.6% for PI. The most prevalent TDRM for NNRTI, NRTI, and PI were K103N (70.3%), M41L (24.8%), and L90M (29.6%), respectively. MSM aged 13–29 had the highest TDRM prevalence (18.6%) and had more TDRM than MSM aged 40–49 (15.9%) (PR=1.17; CI=1.05–1.32). TDRM prevalence did not differ significantly by race/ethnicity: black (17.7%), Hispanic/Latino (17.5%), white
Background: Primary HIV-1 infection can compromise the efficacy of antiretroviral therapy (ART). The prevalence of primary resistance to integrase strand-transfer inhibitors (INSTI) in recently HIV-1-infected subjects remains unknown.

Methodology: This was a multicenter cross-sectional study within the European SPREAD surveillance programme which continuously collects data from a representative set of newly diagnosed patients. A representative set of 300 samples from 1950 patients diagnosed in 2006/2007 was selected from the main cohort. The prevalence of INSTI resistance was evaluated using quality controlled baseline population sequencing of integrate (IN). A subset of 20% were further evaluated using 454 IN sequencing. For both analyses, we assessed major mutations based on the IAS-USA mutation table. All integrase substitutions were classified according to their Stanford HIVdb score ≥10 for at least one INSTI. Minority variants (MV) were defined as substitutions present in 1-20% of viruses in the 454 analysis. Subtypes were determined from population sequencing data using the Rega Subtyping Tool vs 2 based on pol.

Results: For the population sequencing analysis, 279 samples were retrieved and successfully analysed. 67% of isolates were subtype B. No signature resistance mutations to INSTIs (N155H, Q148R/K/Y143R/H/C) were detected. In 11 (4%) patients the following mutations on resistance associated positions were detected with HIVdb score≥10: L74M (n=2; 1%), T97A (n=2; 1%), E138A, A153F, E157Q (n=2; 1%), G163KT, R263K, V151I + G163KR. In 31 (11%) patients mutations with HIVdb score <10 were found: L68I, L68V, L74I (n=13; 4.6%), L74V, T97S, A128T (n=2; 1%), E138D (n=2; 1%), E138G, G140V, V151I (n=6; 2%), 68V + L74V, 143DN + Q146E (n=1; 0.4%). Subsequently 56 samples were analysed with 454 sequencing. Median overall coverage was 4294 reads/substitution. Again, no signature mutations were detected. IN substitutions with HIVdb score≥10 were found in 7 (12.5%) subjects: E157Q in 5 (8.9%) subjects, 1 as MV; H51Y and G163R in 1 (1.7%) subject each, both as MVs; and G163K in 1 (1.7%) individual. IN mutations with HIVdb score <10 were: V151I in 6 (10.7%), 3 as MVs; L74I in 3 (5.3%), 1 as MV; and A128T, N155D, H51Q and T97I in 1 (1.7%) subject each, all as MVs.

Conclusions: As expected, no signature INSTI-resistant variants were circulating in Europe before the introduction of INSTIs, either as high- or low-frequency variants. However, polymorphisms contributing to INSTI resistance were not rare. As INSTI use becomes more widespread, continuous surveillance of primary INSTI resistance is warranted. These data provide a baseline for that purpose and will be key to model the kinetics of INSTI resistance transmission in Europe in the coming years.

Antiretroviral Drug Resistance Among HIV-Infected Black Men Who Have Sex With Men in the US

Iris Chen1, Vanessa Cummings2, Lei Wang3, Matthew B. Connor4, Mark A. Marzinke3, Sheldon D. Fields1, Darrell P. Wheeler4, Kenneth H. Mayer5, 6, Beryl A. Koblin1, Susan H. Ebheme6, for the HPTN 061 Study Team

1Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 2Vaccine and Infectious Disease Division, Fred Hutchinson Cancer Research Center, Seattle, WA, United States, 3College of Nursing and Health Sciences, Florida International University, Miami, FL, United States, 4School of Social Work, Loyola University Chicago, Chicago, IL, United States, 5The Fenway Institute, Boston, MA, United States, 6Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, United States, 7Laboratory of Infectious Disease Prevention, New York Blood Center, New York, NY, United States

Background: In the United States (US), Black men who have sex with men (MSM) are disproportionately affected by HIV. Understanding the current prevalence and patterns of antiretroviral (ARV) drug resistance in this population is important since ARV drug resistance can lead to treatment failure and limit treatment options. We analyzed ARV drug resistance among Black MSM from the HIV Prevention Trials Network (HPTN) 061 study. The HPTN 061 study enrolled 348 HIV-infected Black MSM (classified as newly or previously diagnosed) and 1,167 HIV-uninfected Black MSM from six major cities in the US.

Methodology: The ViroSeq HIV-1 Genotyping System was used to analyze ARV drug resistance in men who had a viral load >400 copies/mL at enrollment (N=171) or seroconversion (N=22). Eighty-three of the 171 men were classified as newly diagnosed (including 3 with acute infection and 11 identified as recently infected using a multi-assay algorithm); 88 were classified as previously diagnosed (including 31 who reported that they were in care). Samples were also tested for the presence of ARV drugs.

Results: Genotyping results were obtained for 168 (98.2%) of the 171 men who were HIV infected at enrollment and for all 22 seroconverters. ARV drug resistance was detected in 48 (28.6%) of the 168 men, including four (36.4%) of 11 men with recent HIV infection: none of the three men with acute infection had resistance. Nineteen (11.3%) of the 168 men had multi-class drug resistance (MCR), including two with resistance to all three major classes
of ARV drugs. Five (22.7%) of the 22 seroconverters also had drug-resistant HIV. The prevalence of drug resistance significantly differed by city: Boston, 7/14=50%; San Francisco, 5/10=50%; Los Angeles, 17/41=41.5%; New York City, 10/50=20%; Atlanta, 5/29=17.2%; Washington DC, 4/24=16.7% (P=0.01). ARV drug testing revealed that some men with ARV drug resistance were on failing ARV treatment regimens. Both ARV drug resistance and MCR were more common among men >30 years of age (P=0.02 and P=0.002, respectively). MCR was more common among men classified as previously diagnosed than among men classified as newly diagnosed (P=0.003) or seroconverters (P=0.02).

Conclusions: ARV drug resistance, including multi-class and transmitted drug resistance, is common among Black MSM in the US. In three of the six cities studied, >40% of the men had resistance. Overall, 11.3% of the men had MCR. Furthermore, 25% of the newly-infected men (acute infection, recent infection, seroconverters) had resistance, which most likely reflects transmission of resistant HIV strains. These findings underscore the public health importance and urgency of scaling up culturally appropriate and acceptable programs to engage Black MSM in care and promote adherence to ARV treatment.

582 Impact of Transmitted Drug Resistance On Susceptibility To First-Line HAART in France (2010-2012)

Marie-Laure Chait1, Lambert Assoumou2, Pierre Frange3, Antoine Cheret4, Laurence Morand-Joubert5, Jean-Christophe Plantier6, Marc Wirden7, Florence Nicot8, Diane Descamps9, Laurence Meyer9, the ANRS AC-11 Resistance Group, the ANRS PRIMO Cohort Study and the OPTIPRIM-ANRS 147 Study Group
1Université Paris Descartes, Paris, France, 2INSEM, UMR-S 943, UPMC Université Paris 6, Paris, France, 3Laboratoire de Virologie, CHU Saint-Antoine, Paris, France, 4Laboratoire de Virologie, CHU Rouen, Rouen, France, 5Laboratoire de Virologie, CHU La Pitié Salpêtrière, Paris, France, 6Laboratoire de Virologie, CHU Toulouse, Toulouse, France, 7Laboratoire de Virologie, AP-HP GHU Bichat-Claude Bernard and EA 4409 UniversitéParis-Diderot, Paris, 7, FRES Sorbonne Paris Cité, Paris, France, 8INSERM, CESP U1018, Université Paris XI, Faculté de Médecine Paris-Sud, Service d’Epidémiologie et de Santé Publique, AP-HP, Hôpital Bicêtre, Le Kremlin-Bicêtre, France

Background: As recommended by the ANRS program for HIV-1 resistance surveillance, we estimated prevalence of transmitted drug resistance mutations (RAMs) and the evolution of the viral molecular epidemiology in primary HIV-1-infected patients in France.

Methodology: 796 primary HIV-1-infected patients were included in 2010-2012 (404 from the AC11 ANRS Group, 302 from the PRIMO Cohort and 90 from the OPTIPRIM trial). Genotypic resistance studies were performed on protease, reverse transcriptase and integrase genes. Reverse transcriptase (RT) and protease mutations were identified from the list for genotypic surveillance of transmitted HIV-1 drug resistance (Bennett et al, 2009). Concerning etravirine (ETR), rilpivirine (RPV) and integrase inhibitors (INI), we used the list of mutations identified from the ANRS resistance algorithm and the latest IAS-USA resistance mutations list. HIV-1 subtype was determined after phylogenetic analysis of the RT sequences.

Results: At inclusion, median viral load and median CD4 cell count were 5.5 log10 copies/ml [range: 1-8.14] and 490 cells/ml [range: 6-1600] respectively. Prevalence of viruses with reverse transcriptase or protease RAMs was 10.7% (796). Prevalence of NRTIs, NNRTIs and PI s RAMs was 5.2%, 7.3% and 2.0%, respectively. RPV and/or ETR RAMs were observed in 3.3%. Resistance to 2 or 3 classes of ARV was observed in 2.4% of patients. Integrate RAMs were observed in 1.5% (5/332, E157Q). Frequency of RAMs was higher in patients infected with B subtype compared to non-B (13.4% (72/535) vs 6.9% (18/261), P=0.006). MSM tended to be more frequently infected with resistant virus than heterosexual patients (12.1% (73/602) vs 8.1% (12/148), P=0.17. We observed an increase in frequency of virus with NNRTIs RAMs in 2010/12 compared to 2005/06 study (7.3% vs 4.6%) because of the recent survey of etravirine and rilpivirine RAMs.

Although subtype B still predominates in France (67%), the frequency of non-B viruses increased significantly in patients with PHI between 2010-2012 (33%) and 1996-1998 (10%). CRF02_AG was the most predominant non-B subtype (53.6%), because of the close links between France and West-African countries. However, we also described 121 strains belonging to 6 other subtypes and 12 other CRFs, and 1 group N virus (found in a patient originated from Togo), reflecting the exceptional viral diversity of the French epidemic.

Conclusions: In France in 2010-2012, the global prevalence of transmitted drug-resistant variants was 10.7% stable since 1996, and higher in B subtype infected patients. However, more than 95% of viruses are sensitive to French and WHO first line recommended HAART.

583 Persistence of Transmitted HIV-1 Drug Resistance Mutations Associated With Fitness Costs

Wen-Lin Y. Yang1, Roger Koyou2, Jürg Bünli3, Sabine Yerli4, Thomas Klimkait4, Vincent Aubert5, Christos Petropoulos6, Molgan Haddad5, Sebastian Bonhoeffer7, Huldrych F. Günthard7, Swiss HIV Cohort Study (SHCS)
1University Hospital of Zurich, Zurich, Switzerland, 2University of Zurich, Zurich, Switzerland, 3University of Geneva, Geneva, Switzerland, 4University of Basel, Basel, Switzerland, 5Lausanne University Hospital, Lausanne, Switzerland, 6Monogram Biosciences, San Francisco, CA, United States, ETH, Zurich, Switzerland

Background: Transmitted HIV-1 drug resistance mutations (TDR) can impair antiretroviral treatment (ART) but the persistence of many TDRs is poorly understood. We determined persistence times for TDR in treatment-naive patients from longitudinal genotypic resistance tests (GRT) from the Swiss HIV Cohort Study Drug Resistance Database, and compared persistence times with fitness cost of TDRs.

Methodology: TDR were defined according to the WHO surveillance list. Sequential plasma samples from treatment-naive individuals carrying TDR within the protease (PR) or reverse transcriptase regions (RT) were retrospectively sequenced. All GRT from treatment-naive individuals with ≥ 2 GRT and TDR at baseline were included. We performed a Kaplan-Meier survival analysis for each single TDR carried by ≥ 5 individuals at baseline. We used Poisson regression to infer reversion rates (RR) for each TDR and thus were able to quantify persistence times. We estimated fitness costs of TDR in the genetic background in which they occurred. To this end we used a previously published and validated machine learning algorithm based on 70000 in vitro replicative capacity measurements from Monogram Biosciences. Since negative fitness costs of resistance mutations are not reliable predictors, we focused the analysis on mutations with positive median fitness costs. Hazard Ratios (HR) were calculated with Cox-proportional-hazard models.

Results: Retrospective PR/RT sequence analysis was conducted on 918 samples from 210 treatment-naive patients. Filling all criteria, we included 633 sequential GRT from 155 treatment-naive patients for our analysis. Twenty-one TDR were analyzed: NRTI=12, PI=6, and NNRTI=3. Persistence times varied considerably. Among all, the shortest persistence was the NRTI mutation T215Y with a reversion rate (RR) per 100 person-years (95% CI) of 72.71

Acquired HIV Drug Resistance

584  High HIV Resistance and Mutation Accrual at Low Viral Loads Upon 2nd-Line Failure in Western Kenya
Lameck Diero1,2, Allison DeLong3, Leaann Schreier4, Emmanuel Kemboi5, Millicent Orido6, Mary Reno6, Marissa Reitsma6, Wilfred Emonyi7, Nathan Buziba3, Joseph Hogan3, Rami Kantor4
1Medicine, Moi University, College of Health Sciences, School of Medicine, Eldoret, Kenya, 2Academic Model Providing Access to Healthcare, Eldoret, Kenya, 3Center for Statistical Sciences, Brown University, Providence, RI, United States, 4Medicine, Brown University, Providence, RI, United States

Background: World Health Organization (WHO) defines antiretroviral treatment (ART) failure as HIV viral load (VL) >1000 copies/mL in resource limited settings (RLS). 2nd-line ART failure with drug resistance can limit subsequent regimens, more in settings with limited VL and resistance testing and delayed failure diagnosis. Resistance data upon 2nd-line failure in RLS are limited, particularly below the WHO VL threshold.

Methodology: We examined 2nd-line failure, drug resistance and their correlates in western Kenya, in patients on ≥6 months lopinavir/ritonavir-based 2nd-line, after ≥6 months prior 1st-line ART. Patients with detectable VL had pol genotyping and follow-up peripheral blood mononuclear cells (PBMC) and plasma re-genotyping.

Results: 401 patients were enrolled, mean age 42 years, 60% female, median CD4 278 cells/μL, mean detectable VL 52,480 copies/mL, median 1.9 years on 2nd-line, median 2.8 years on prior 1st-line ART. 49% had detectable VL>40; 24% >1000 copies/mL. Lower CD4 count (Odds Ratio (OR) 0.70 per 100 cells, p<0.001), longer duration of ART interruption on 1st-line (OR 1.18 per month, p=0.03), shorter time on 2nd line (OR 0.83 per year longer, p=0.008), tuberculosis treatment on 2nd-line (OR 2.67, p=0.01), and ≥1 pregnancy (OR 2.35, p=0.01) were associated with VL>1000. 182 genotypes were available (109 plasma; 73 PBMC), 57% subtype A, 24% D and 19% other. Any plasma resistance was seen in 78%; 67% to nucleoside reverse transcriptase inhibitors (NRTIs), 73% non-NRTIs (NNRTIs) and 8% protease inhibitors (Pis); 63% had 2 or 3-class resistance. Archived resistance were available (109 plasma; 73 PBMC), 57% subtype A, 24% D and 19% other. Any plasma resistance was seen in 78%; 67% to nucleoside reverse transcriptase inhibitors (NRTIs), 73% non-NRTIs (NNRTIs) and 8% protease inhibitors (Pis); 63% had 2 or 3-class resistance. Archived resistance was seen in 84% of available sequences from patients with detectable VL<1000. Patients with VL<1000 had more resistance mutations than those with VL≥1000 (rate ratio 1.47, p=0.02), mostly due to NRTI mutations (rate ratio1.89 p=0.002). Of 48/109 patients with follow up sequences after median 1.8 months on similar 2nd-line, 42% accumulated mutations, responsible for a predicted increase to intermediate or high-level resistance in 70% of patients. Of those, 8/20 (40%) patients had VL<1.000. Factors associated with resistance accumulation included higher CD4 (OR=1.55 per 100 cells higher, p=0.03), male gender (OR=3.92, p=0.04), older age (OR=1.07 per year older, p=0.04), and WHO stage 1 (OR=7.0, p=0.03).

Conclusions: We report high rates of 2nd line ART failure, circulating and archived drug resistance and resistance accumulation in a large HIV treatment program in western Kenya, including at VL levels below the WHO threshold for ART failure. These findings mandate careful strategic planning for ART and for VL and resistance monitoring in RLS.

585  Drug Resistance After 2nd-Line Failure Can Be Managed Using WHO-Recommended Regimens in Nigeria
Nicaise Ndembi1, Rawlings W. Datir1, Danjuma Sanda1, David A. M. C. van de Vijver2, Christopher Akolo3, Alash‘le G. Abimiku4, William A. Blattner2, Obinna Ogbanufe4, Okey C. Nwanyanwu4, Patrick Dakum1
1Institute of Human Virology Nigeria, Abuja, Nigeria, 2Virology, Erasmus Medical Center, Erasmus University, Rotterdam, Netherlands, 3Epidemiology and Prevention, Institute of Human Virology, Baltimore, MD, United States, 4US Centers for Disease Control and Prevention, Abuja, Nigeria

Background: In sub-Saharan Africa only a limited number of antiretroviral drugs is available. Virological failure, and subsequent drug resistance, during second-line treatment can therefore have substantial clinical ramifications as it can result in complete loss of therapeutic options. The Institute for Human Virology-Nigeria (IHVN), a US PEPFAR implementing partner, provides antiretroviral therapy (ART) to over 150,000 public and private sector patients through the AIDS Care and Treatment in Nigeria (ACTIONPlusUp) Program. We determined the extent to which virological failure during second line treatment with LPV/r, ATV/r results in the loss of treatment options to WHO recommended treatment regimens at two IHVN PEPFAR supported sites in Abuja.

Methodology: Plasma samples from patients who failed LPV/r and ATV/r- based second-line regimens from January to August 2013 were assayed for HIV-1 RNA viral load (VL). Plasma virus from samples with VL >1000 cp/mL at time of failures were sequenced in the pol gene. The genotypes were interpreted using the Stanford HIV db interpretation program (version 6.3.1). We assigned the following genotypic susceptibility scores (GSS) to the 5 levels of resistance included in the Stanford HIV db program: 0, 0.25, 0.50, 0.75, and 1 for respectively the high-level resistance, intermediate resistance, low-level resistance, potential low-level resistance, and susceptible. We then calculated the GSS to the first-, second-, and third-line regimens recommended by WHO as the arithmetic sum of the individual GSS. We defined loss of drug options as a GSS of zero to any WHO recommended regimen. Exhaustion of drug options was defined as a GSS<2.
Results: Of the 936 HIV-infected patients receiving second-line ART, 56 (6.0%) were adults with confirmed virological failure. The mean (SD) HIV RNA and age were 5.1log10 (0.79) cp/mL, and 34.8 (15.6) years, respectively. A total of 10 sequences contained no drug resistance mutations. The five most frequently observed mutations were K103N (22.4%), M184V (20.4%), M41L (20.4%), M46I (19.4%) and I54V (15.3%). Complete loss of treatment options was only found in one patient (2%), with virus still susceptible to a second generation NNRTI. Exhaustion of drug options to first- and second line regimens was found in 16 patients (32%). If second generation NNRTIs and newer boosted protease inhibitors become available, then exhaustion of drug options will be reduced to 22%.

Conclusions: Complete loss of treatment options is very rare after failure to second-line treatment in Nigeria. Exhaustive loss of treatment options occurs in less than one out of three patients and can be partially avoided by providing third-line regimens. In most patients an active treatment regimen can be given after failure with second-line treatment.

586 Sociodemographic Determinants of HIV Drug Resistance in British Columbia, Canada
Chanson J. Brumme1, Melanie Rusch2,3, Keith Chan1, Dmitry Shopin1, Guillaume Colley1, Zabrina L. Brumme1,4, Robert S. Hogg1,4, Julio S. G. Montaner1,5, P. Richard Harrigan1,5
1BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 2Vancouver Island Health Authority, Victoria, BC, Canada, 3School of Public Health and Social Policy, University of Victoria, Victoria, BC, Canada, 4Faculty of Health Sciences, Simon Fraser University, Burnaby, BC, Canada, 5Division of AIDS, University of British Columbia, Vancouver, BC, Canada

Background: Baseline clinical factors and adherence to HAART are associated with resistance development after therapy. However, the interplay between sociodemographic and clinical factors influencing resistance development has not been well examined at a population level.

Methodology: A cohort of HIV-positive persons accessing treatment from the BC-CIE Drug Treatment Program (DTP) from 1996-2012 was followed longitudinally. Census-level sociodemographic (SD) predictors of uptake of HIV drug resistance testing were determined using multivariable GEE logistic regression. The determinants of the emergence and detection of drug resistance in the subset of ARV-naïve persons initiating HAART in the BC-CIE DTP was assessed with Weibull survival analysis. In brief, patients were grouped by Census Tract (CT) of residence at time of enrollment. Census level SD variables (population density, % single family housing, % immigrants, median income, education and unemployment levels) were assigned by CT. Models were adjusted for individual level clinical variables including baseline plasma viral load, CD4, gender, age, risk factors, physician experience and adherence. All available HIV protease-RT sequences (N=33,000) were used.

Results: A total of 11,083 DTP patients, including a subset of 5381 ARV-naïve at HAART initiation, were followed longitudinally. Of the 9310 (84%) patients with at least one post-therapy plasma sample eligible for testing (pVL>250 c/mL) only 4751 (51%) had a physician-ordered resistance test; however the proportion of samples tested markedly increased with calendar year (p<0.001). In univariate models, all SD variables investigated were significantly associated with uptake of testing and/or development of HIV resistance. After adjustment for individual-level clinical variables and adherence, an increased hazard for first resistance event was observed for persons living in CTS with higher unemployment levels (HR 1.08; p=0.004 per 10% increment) driven largely by the emergence of 3TC/FTC resistance (HR 1.12; p<0.001). However, persons living in CTS with higher proportions of single family residences (HR 0.65; p=0.01) and post-secondary education (HR 0.92; p=0.009 per 10% increment) were at decreased risk of NNRTI resistance. No SD factors were associated with resistance to other NRTIs or PIs.

Conclusions: HIV drug resistance was observed across all sociodemographic strata regardless of adherence levels. Unemployment rate within a census tract, a surrogate for lower socioeconomic status, was associated with an increased risk of resistance. However, the complex relationship between census-level SD variables makes it difficult to identify specific social groups or geographic locations at higher risk of developing resistance in BC.

587 Week 144 Resistance Analyses of the Phase 3 EVG/COBI/FTC/TDF Studies
Rina Kulkarni, Michael E. Abram, Martin S. Rhees, Marshall W. Fordyce, Javier Szwarzberg, Michael D. Miller, Kirsten L. White
Clinical Virology, Gilead Sciences, Inc., Foster City, CA, United States

Background: Two phase 3, randomized, blinded, studies of elvitegravir/cobicistat/emtricitabine/tenofovir DF (EVG/COBI/FTC/TDF) in treatment-naive subjects are ongoing (Studies 102 and 103). The week (W) 144 responses (Missing = Failure) were durable and similar for EVG/COBI/FTC/TDF vs. efavirenz (EFV)/FTC/TDF (82% vs 78%) and EVG/COBI/FTC/TDF vs. ritonavir-boosted atazanavir (ATV+RTV)+FTC/TDF (81% vs 79%). Resistance analyses through W144 are presented.

Methodology: HIV-1 genotypes (PR and RT) were analyzed at screening (GeneSeq, Monogram Biosciences); subjects with resistance to FTC, TDF, EFV, or ATV were excluded based on study. Retrospective integrase (IN) genotyping was conducted on 363 EVG/COBI/FTC/TDF baseline samples. Virologic failures had genotypic/phenotypic analyses at confirmed failure and baseline for PR, RT, and IN, or at first failure (EVG/COBI/FTC/TDF only) (Monogram and Labcorp).

Results: EVG/COBI/FTC/TDF subjects with baseline PI (N=18) or NNRTI mutations (N=95) including K103N in RT (N=27, Study 103) had high virologic response through W144 (62% for K103N). Baseline primary IN strand transfer inhibitor (INSTI) mutations were rare (N=4/337); all EVG/COBI/FTC/TDF subjects with T97A [N=1] and Y143H [N=1] rapidly suppressed and had W144 HIV-1 RNA <50 c/mL. In the EVG/COBI/FTC/TDF groups through W144, 18 subjects (2.6%; 18/701) developed primary INSTI (N=15) and/or NRTI resistance mutations (N=17) (Any resistance: 13 through W48, 3 between W48-W96, and 2 between W96-W144). Emergent INSTI mutations were E92Q (N=9), N155H (N=5), Q148R (N=3), T66I (N=2) and T97A (N=1) and emergent NRTI mutations were M184V/I (N=17) and K65R (N=5). In the EFV/FTC/TDF group, 14 subjects (4.0%; 14/352) developed drug resistance (8 through W48, 2 between W48-W96, and 4 between W96-W144) and was most commonly K103N (N=13) with M184V/I (N=4) plus K65R (N=3) in RT. In the ATV+RTV+FTC/TDF group, 2 subjects had M184I emerge post-W96. The first failure samples from 16 STB patients with emergent resistance were given after failure with second-line treatment.
Poster Abstracts

Conclusions: Treatment with EVG/COBI/FTC/TDF achieved durable high rates of virologic suppression in HIV-1 treatment-naïve subjects, including subjects with pre-existing NNRTI or PI resistance. Resistance development was infrequent (2.6% of STB-treated subjects). The most common patterns of resistance mutations to EVG/COBI/FTC/TDF were E92Q, Q148R, or N155H in IN with M184V/I in RT which were more readily detected at the confirmed virologic failure timepoint.

Emergent and Detectable Proviral DNA Drug Resistance in a Community Treatment Program
Anne Derache1, Hyoung Shik Shin2, Elizabeth White1, Dennis Israelni3, Jeffrey D. Klausner3, David Katzenstein1, Peninsula AIDS Research Collaboration
1Medical School / Infectious Diseases, Stanford University, Stanford, CA, United States, 2Center for Infectious Disease, National Medical Center, Seoul Korea, Seoul, Republic of Korea, 3David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, United States

Background: Drug resistance mutations (DRM) may circulate in HIV RNA and persist in CD4 cell DNA despite antiretroviral therapy (ART). To determine risks for transmission and community reservoirs of DRM, DNA genotype was assessed from PBMC DNA of viremic and suppressed ART recipients in a community clinic population.

Methodology: HIV-1 sequences from consecutive consenting patients on ART were enrolled and followed 6 monthly for 2 years. Viremic subjects (>50 copies/ml of RNA) had genotypes from plasma RNA and PBMC DNA, and those suppressed (< 50 copies/ml of RNA) from PBMC DNA only. Phylogenetic relationships were inferred using the Neighbor Joining method, with 2 Kimura parameters and 1000 bootstrap replicates. Statistical comparisons of median values were performed by non-parametric Rank-sum tests.

Figure 1: Neighbor Joining of pol sequences from proviral DNA, with 1000 bootstrap replicates. ● = NRTI resistance (25) ■ = NNRTI resistance (17) and ▲ = PI (5) resistance. Shaded sequences the cluster of 17 AA.
Results: Of the 124 individuals (27 female, 96 male and 1 transgender) 35 were African-American (AA), 30 Hispanic, 12 Asian and 47 White. The 38 viremic subjects had a median viral load and CD4 cell count of 5,865 copies/ml and 298 cells/mm³; 24/38 (63%) were wild-type (WT) and 12 (27%) had the same DRM in both RNA and DNA (concordance of 89%). Two had M184V in DNA but not in RNA and 2 in RNA but not DNA. Among the 12 with DRM, the median CD4 was significantly lower compared to those who were WT, 276 vs 381 cells/mm³ (p<0.01).

Among 86 suppressed individuals, 37/86 (43%) had one or more archival DRM; 9 had 2 classes and 1 had 3 classes of DRM. CD4 cells counts were similar between 35 with and 51 without DNA DRM (413 vs 427 cells/mm³).

Eleven of 86 (13%) of those suppressed at entry developed virologic failure by 48 weeks. DRM developed in plasma RNA of 6/11 (55%), 3 who were DNA WT and 3 with DNA DRM at entry.

Phylogenetic analysis (Fig 1) showed related sequences included 2 pairs of men with bootstrap values of 97 and 99 % and one trio (2 men and 1 woman) 61%. Seventeen older AA injection drug users (IDU) clustered with a low bootstrap value (45%).

Conclusions: Analysis of DNA genotype may guide treatment and identify transmission networks. DRM in archival DNA may pose a risk of transmission and re-emergence of resistance at failure and may limit future treatment options. The weak bootstrap linkage among a cluster of 17 older AA men and women who were former IDU, suggests a distant founder effect in this population.

589 Acquired Drug-Resistance Mutations and Mortality Among HIV Patients On First-Line ART
Julia W. Wu¹, Hui Xing², Eric Tchetgen Tchetgen¹-², Lingjie Liao³, Shahin Lockman³, Yuhua Ruan³, Victor De Gruttola³, Marc Lipsitch¹, George R. Seage¹, Yiming Shao²
¹Department of Epidemiology, Harvard School of Public Health, Boston, MA, United States, ²National Center for AIDS/STD Control and Prevention, Chinese Center for Disease Control and Prevention, Beijing, China, ³Department of Biostatistics, Harvard School of Public Health, Boston, MA, United States, 4Department of Immunology and Infectious Diseases, Harvard School of Public Health, Boston, MA, United States

Background: The potential long-term clinical risks of staying on failing nucleoside reverse-transcriptase inhibitor/non-nucleoside reverse-transcriptase inhibitor (NRTI/NNRTI)-based first-line antiretroviral treatment (ART) regimens and acquired drug-resistance mutations (DRMs) have not been well elucidated.

Methodology: The study population included adult HIV patients who were initially ART-naive and who started first-line regimens between 2003-2005 at two sentinel sites in China. ART regimens were either AZT/DDI/NVP or D4T/DDI/NVP, primarily. Given the national treatment program policy at that time, patients had no access to protease-inhibitor-based second-line regimens and remained on first-line despite virologic failure for prolonged periods. HIV RNA and CD4 testing were performed at pre-ART baseline and every 6 months (including after virologic failure). Patients with HIV RNA>1,000 copies/ml on ART had longitudinal genotyping to test for drug resistance. We estimated the effects of acquired DRMs on mortality, using marginal structural models to account for time-varying confounding.

Results: Five hundred seventeen patients were included. After median 58 months follow-up, 404 (78%) patients had HIV RNA>1,000 copies/ml at least once, and 291 (56%) of the 517 had DRMs. At initial detection of DRMs, all patients but one had >1 NNRTI-class mutation and 63% had both NRTI- and NNRTI-mutations. Seventy six (15%) patients died. Patients were more likely to develop DRMs if they had HIV RNA > 10,000 copies/ml at baseline (HR=1.42) or at the previous visit (HR=1.39), CD4 count < 350 cells/mm³ at the previous visit (HR=1.92), no education beyond elementary school (HR=1.35), used alcohol (HR=1.43), were farmers (HR=1.49), initiated ART in 2003 (HR=2.77) or 2004 (HR=1.79). The mortality hazards ratio for acquired DRMs was 2.49 (95% confidence interval: 1.38-4.51) after adjusting via inverse-probability-weights (IPW) for baseline (including age, gender, occupation, site, education level, marital status, alcohol use, calendar time of treatment initiation, level of initial adherence, baseline CD4 count and viral load) and time-varying confounders (modification of first-line ART regimens, CD4 count and HIV RNA at the previous visit). The hazard ratio increased over time since first detection of DRMs (see Figure 1).

Conclusions: We identified an elevated risk of mortality associated with acquired DRMs. The excess risk increased with time since first detection of DRMs.

Figure 1. IPW hazard ratios for mortality with the development of any DRM versus no mutation, over time
590LB PrEP Exposure and the Risk of Low-Frequency Drug Resistance

Dara A. Lehman1, Jared Baeten2, Connor McCoy3, Julie F. Weis3, Dylan Peterson4, Connie Celum1, Nelly Mugo4, Julie Overbaugh1, Frederick Matsen4, the Partners PrEP Study Team

1Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA, United States, 2Department of Global Health, University of Washington, Seattle, WA, United States, 3Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, United States, 4Department of Obstetrics and Gynecology, University of Nairobi, Nairobi, Kenya

Background: Pre-exposure prophylaxis (PrEP) reduces HIV acquisition. However, for those who acquire HIV while receiving PrEP there is the potential for drug resistance to arise as a result of partial HIV suppression through PrEP medication exposure before HIV seroconversion is detected. The level of resistance selected by PrEP may not be detectable with standard sequencing methods, which only detect resistance present at frequencies above 20% of the viral population. Studies of antiretroviral treatment failure have suggested that resistance as low as 1% may be clinically significant during subsequent antiretroviral use. 454 ultra-deep sequencing can detect resistance at frequencies below 1%.

Methodology: In the Partners PrEP Study, a randomized trial of daily oral tenofovir disoproxil fumarate (TDF) or tenofovir plus emtricitabine (FTC), plasma samples from the time of HIV seroconversion were tested for predefined mutations that could be selected by TDF (K65R and K70E) and FTC (K65R and M184IV) using 454 ultra-deep sequencing. Samples were considered resistant if the proportion of mutant sequences was significantly above that observed in wild-type genotype-matched controls using Fisher’s exact test with correction for a 5% false-discovery rate. Plasma levels of tenofovir were measured among seroconverters in the active PrEP arms at the time of seroconversion. Fisher’s exact test was used to determine associations with resistance.

Results: A total of 121 seroconverters were tested: 38 had received TDF, 25 FTC-TDF, and 58 placebo. PrEP-related resistance mutations (K65R, K70E and/or M184IV) were detected in 9 (7.4%) at levels >1%, 2 of which had previously been detected by standard sequencing. In the TDF arm, 2 of 38 (5.3%, p=0.65 vs placebo) had resistance >1%: 1 had K65R/K70E and 1 had M184IV. In the FTC-TDF arm, resistance was detected in 5 of 25 (20%, p=0.024 vs placebo): 4 had M184IV and 1 had M184IV/K65R. Two of the 58 (3.5%) placebo participants had M184IV resistance. Resistance was detected in 3 individuals retrospectively determined to be HIV infected (seronegative but RNA positive) when PrEP was initiated, and in 6 individuals infected after PrEP start. In seroconverters in the active PrEP arms, PrEP use was associated with higher risk of resistance: 6 of 23 (26%) with measurable drug levels versus only 1 of 39 (2.6%) without evidence of PrEP use had resistance >1% (p=0.009).

Conclusions: High-sensitivity resistance testing detected more resistance than standard sequencing in persons acquiring HIV who were exposed to PrEP, although resistance still occurred in a minority of subjects. More resistance was selected by FTC than TDF, as evidenced by the prevalence of M184IV compared to K65R.

591 Rilpivirine-Associated Resistance in HIV-1 DNA in Suppressed Patients Pretreated by NNRTIs

Sebastien Gallien1, Isabelle Charreau2, Marie-Laure NERE3, Nadia Mathjub4, Nathalie de Castro5, Jean-Pierre Aubulker6, Jean-Michel Molina7, Constance Delaugerre8

1Infectious Diseases, Hôpital Saint Louis, Paris, France, 2Essais Thérapeutiques et Maladies Infectieuses, INSERM SC10 - US019, Villejuif, France, 3Virology, Hôpital Saint Louis, Paris, France, 4INSERM SC10 - US019, Villejuif, France

Background: First generation NNRTI (efavirenz and nevirapine) failure is associated with a rapid selection of resistance-associated mutations (RAMs) which may impact on etravirine or rilpivirine susceptibility. Unfortunately in well suppressed patients historical resistance genotypes from plasma do not provide information regarding rilpivirine and etravirine-resistance. Our objective was to determine the presence of RAMs to rilpivirine, etravirine and the combination of tenofovir/emtricitabine/rilpivirine on HIV-1 DNA from patients enrolled in the ANRS Easier Trial.

Methodology: All 169 patients enrolled in the ANRS 138-EASIER trial were treatment-experienced, have received three antiretroviral drug classes (NRTI, NNRTI and PI) and had plasma HIV-1 RNA <400 cp/ml at baseline. Patients were treated for a median of 13.6 years and were controlled for at least 2 years. Treatment regimens at baseline were NRTIs (95%), PIs (99%), and NNRTIs (8%). Reverse transcriptase gene (RT) sequencing was performed on extracted HIV-1 DNA from whole blood at the time of inclusion. We analysed the pattern and the prevalence of RAMs to rilpivirine, etravirine, tenofovir and emtricitabine according to the 2012 ANRS v22 algorithm.

Results: RT gene amplification was successful in 128/169 (76%) patients and 95% of HIV-1 as subtype B. Rilpivirine RAMs were detected in 40/128 (31%) of patients, with highest frequency for the mutations Y181C/I/V (23/40, 18%), K101E/P (9/40, 7%) and E138A/G/K/Q/R/S (8/40, 6%). Efavirenz RAMs were detected in 5/128 (4%) of patients. Resistance to emtricitabine and tenofovir were detected in 72/128 (56%) and 12/128 (9%), respectively. Resistance to at least one drug included in the combination of tenofovir/emtricitabine and rilpivirine was observed for 88/128 (69%) patients.

Conclusions: In patients with suppressed viremia under ART, but who had previously failed efavirenz and/or a nevirapine-based regimen, the prevalence of resistance in HIV-1 DNA was high for rilpivirine (31%) and for the combination of tenofovir/emtricitabine/rilpivirine (69%). Conversely, resistance to etravirine was rare (4%). This result confirms that the switch to rilpivirine-based regimen should not be recommended in patients that previously failed to efavirenz and/or nevirapine-containing treatment.

592 Etravirine/Rilpivirine-Specific Mutations Selected by EFV and NVP in Kenyan Patients Failing ART

Keith W. Crawford1, Dorothy Njera1, Jonah Maswai2, Milton Omondi3, Jane Kinetto3, Duncan Apollo4, Appolonia Aoko4, Raphael Langat4, Lawrence Gitano4, Jemutai Tarus4, Tiffany E. Harmon1

1Global Health Programs, US Military HIV Research Program, Bethesda, MD, United States, 2US Army Medical Research Unit-Kenya (USAMRU-K), Nairobi, Kenya, 3US Army Medical Research Unit-Kenya (USAMRU-K), Kericho, Kenya, 4US Army Medical Research Unit-Kenya (USAMRU-K), Kisumu, Kenya

Background: Antiretroviral drugs may produce different mutation patterns in different HIV-1 subtypes. We report here on the appearance of drug resistance mutations unique to etravirine and rilpivirine exposure occurring in Kenyan patients with non-B subtypes failing first line therapy with nevirapine or efavirenz.
HIV-1 Resistance Outcomes in Seroconverters From MTN 003 (VOICE)

Abstract Listing

Background: The emergence of drug resistance is a major concern when using antiretroviral agents for HIV prevention. Of six HIV prevention trials that included tenofovir (TFV)-based study products, only 3 cases of resistance have been reported in 155 participants who acquired HIV after enrollment and seroconverted on product. We evaluated seroconverters in MTN 003 (VOICE) for TFV, emtricitabine (FTC) and transmitted resistance.

Methodology: VOICE was a safety and effectiveness study of TFV-based products for HIV prevention conducted at 15 sites in South Africa, Zimbabwe and Uganda. Participants were randomized to vaginal TFV 1% gel, oral tenofovir disoproxil fumarate (TDF), oral FTC/TDF, or oral or gel placebo. Plasma for resistance testing was collected as soon as HIV infection was confirmed, a median of 13 days (IQR 16 days) after seroconversion was detected by a positive rapid test and the participant had been withdrawn from study product. Population sequencing of the protease and reverse transcriptase (RT) genes (ViroSeq, Abbott) was performed on seroconverters with plasma HIV-1 RNA levels ≥ 200 copies/ml using kit-provided or alternate primers. Resistance mutations were identified using the Stanford Genotypic Resistance Interpretation Algorithm.
**Results:** HIV-1 genotypes were obtained for 355/368 (96%) participants, including 21/22 infected at enrollment, 301/312 HIV-1 seroconverters on study product, and 33/34 who were seroconverted between product cessation and study termination. Of the 212 participants in TFV gel, TDF or TDF/FTC arms, no participant had resistance to tenofovir (K65R or K70E). Only 1/55 (1.8%) seroconverter randomized to TDF-FTC who acquired HIV-1 after enrollment developed M184M/V after 309 days on product. Of 9 participants on the TDF-FTC arm already infected at enrollment, 2 (22%) developed M184M/I/V after 26 and 29 days of reported product use. 8/355 (2.3%) participants from all arms had transmitted resistance to nevirapine or efavirenz (K103N/V106M and/or Y181C) while 34 (9.6%) participants had additional RT mutations from the 2009 World Health Organization transmitted drug resistance list, including A62V, D67N, T69N, K70R, V90I, A98G, K101E, V106I, E138A/K, V179E/D/T, T215A and H221Y.

**Conclusions:** Acquired resistance to antiretroviral products used for HIV prevention was rare (1 of 212 participants receiving active product), with no cases of TFV resistance and one case of FTC resistance. Transmitted RT inhibitor resistance (12%) was more likely than acquired resistance to product (<1%). Low product use in the VOICE trial could explain the low frequency of acquired resistance. Better point-of-care tests are needed to exclude acutely infected individuals from prevention trials.

**595 Impact of Raltegravir/Elvitegravir Selected Mutations On Dolutegravir Cross-Resistance**

**Wei Huang, Arne Frantzell, Jeannette M. Whitcomb, Christos J. Petropoulos**

Monogram Biosciences, South San Francisco, CA, United States

**Background:** Mutations at position 148 of HIV integrase (IN) represent a major mutational pathway leading to raltegravir (RAL) and elvitegravir (EVR) resistance. Viruses containing certain Q148 mutation profiles are associated with poor dolutegravir (DTG) treatment responses. In this study, we investigated the effect of Q148H/K/R mutations and other RAL/EVG resistance associated IN mutations on DTG susceptibility using panels of patient-derived viruses and site-directed mutants (SDMs).

**Methodology:** Patient-derived viruses (N=210) containing Q148H/K/R mutations were identified by conventional nucleic acid sequencing. SDMs containing Q148H/K/R mutations alone and in combination with one or more additional IN mutations (L74I/M, E92Q, T97A, E138A/D/K/T, G140A/C/S) were constructed. DTG susceptibility was determined using a pseudovirus luciferase reporter assay (PhenoSense HIV Integrase).

**Results:** Patient viruses containing Q148H/K/R mutations displayed reduced DTG susceptibility with a median fold change in IC_{50} (FC)=4.6 (range 1.7 to 96.0). Q148K viruses that emerge less frequently than Q148H/R variants exhibited larger reductions in DTG susceptibility compared to Q148H/R viruses. All patient viruses contained one or more additional IN mutations with G140 substitutions occurring most frequently followed by E138 substitutions. Based on the analysis of a panel of SDMs, a single mutation at position 148 did not reduce DTG susceptibility (DTG FC=0.5 to 0.7). However, the addition of a second mutation at position 140 conferred measurable reductions in DTG susceptibility (FC=2.2 to 58). The further introduction of additional mutations at positions 74, 92, 97 and 138 conferred incremental reductions in DTG susceptibility. Q148K SDMs containing additional mutations displayed larger reductions in DTG susceptibility than corresponding Q148H/R SDMs, consistent with measurements in patient viruses.

**Conclusions:** In this study, we evaluated a large panel of patient viruses and site-directed mutants to fully characterize the degree of DTG cross resistance that is conferred by Q148H/K/R mutations in combination with additional RAL/EVG resistance associated mutations.

---

**596 N348I in HIV-1 RT Confers Resistance To Etravirine and Rilpivirine But Restricts the Advent of E138K**

Veronica Zanichelli, Hong-Tao Xu, Susan Colby-Geminarino, Maureen Oliveira, Yingshan Han, Yudong Quan, Mark Wainberg, Chen Liang

McGill AIDS Centre, Lady Davis Institute, Montreal, QC, Canada

**Background:** E138K and M184I are mutations associated with clinical resistance to Rilpivirine (RPV) that compensate each other in regard to fitness deficits conferred by each mutation alone (the M184I is a mutation that confers resistance to FTC, a NRTI often used in association with RPV). This was never demonstrated to happen spontaneously for E138K and M184V/I as a result of treatment failure involving FTC. In order to understand the reasons behind this different behavior of the virus we concentrated our attention on N348I. N348I is a mutation in the connection domain of RT that commonly emerges in treatment experienced patients and that is strongly associated with M184V. N348I compensates for the deficit in enzyme processivity behind this different behavior of the virus we concentrated our attention on N348I. N348I is a mutation in the connection domain of RT that commonly.

We wished to analyze this mutation alone and in association with M184I to assess if N348I can prevent or delay the emergence of E138K under Etravirine and RPV pressure and what the impact is of this mutation on viruses that present E138K.

**Methodology:** Site directed mutagenesis was used to construct the plasmids harboring the desired mutations. Selection studies under drug pressure were done in C8Ms and the measurement of HIV replication kinetics was assessed on the basis of p24 levels. To verify the replicative capacity of the recombinant clones containing the mutations a competitive assay was done using TZM-bl cells. These cells were used also for the analysis of phenotypic drug susceptibility. Reverse transcriptase expression and purification were assessed and the susceptibility of RT inhibitors was tested by DNA dependent DNA polymerase activity using recombinant RT enzymes. The processivity of recombinant RT proteins was analyzed using heteropolymeric RNA template.
**597** Analyses of Accessory Mutations in HIV-1 Protease Reveal Interdependent Mechanisms of Resistance

Debra A. Ragland, Madhavi N.L. Nalam, Aysegül Ozen, Yuleng Cai, Hong Cao, Celia A. Schiffer
Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, United States

**Background:** The HIV-1 protease is crucial to the maturation of budding virions. Low adherence to protease inhibitors due to toxicity cause both primary active site mutations, which result in a loss of enzymatic fitness, and accessory mutations, which restore fitness and stability of the enzyme, to arise. The contribution of accessory mutations in conferring drug resistance has been studied in detail but remains elusive. Discerning the synergy of both types of mutations to sustain resistance to highly potent inhibitors while perpetuating viral longevity is the basis of this study. Kinetic and structural analyses of four accessory mutations have revealed possible interdependent mechanisms of mutations beyond the active site and their role in drug resistance.

**Methodology:** In this study, four HIV-1 protease mutants, L76V, L90M, V32I, and V32I+L33F, were characterized for their impact on Darunavir inhibition. Each of the mutants was first tested for DRV susceptibility using a FRET based kinetics assay that measures the fluorescence intensity readout of a hydrolyzed Matrix-Capsid substrate mimic. Each of the four mutants were then co-crystallized with DRV and characterized for changes in static Cα distances, hydrogen bonding, and van der Waals contacts. Using the trajectories from 10ns molecular dynamics simulations the root mean square deviations and fluctuations for each mutant complex was assessed. The trajectories from the simulations were also used to calculate distances for inter and intra- monomeric active site residue pairs to determine the bearing of accessory mutations on active site residues.

**Results:** Although the four mutations observed in this study do not directly lie within the active site or bind to DRV they each impact various aspects of DRV inhibition including a 22.5 fold change in KI exhibited by the V32I+L33F double mutant. Analyses of the co-crystal structures reveal that while no major changes can be observed in both overall structure and static Cα distances, there are significant changes in van der Waals contacts upon the introduction of L33F. Results from molecular dynamics simulations suggest that each mutation affects DRV binding via a network of intra-monomeric main chain polar contacts to reduce protease susceptibility to DRV by altering the conformations of residues within the active site.

**Conclusions:** The interdependent mechanisms of resistance employed by the accessory mutations in this study account for loss of susceptibility to one of the most potent HIV-1 protease inhibitors. Detailed structural analyses employing similar methodologies described above could potentially lead to further discernment of the synergy of accessory mutations and aid in proactively meliorating the current HIV-1 protease inhibitor armamentarium.

---

**598LB** Two Distinct Mechanisms of Resistance To Allosteric HIV-1 Integrase Inhibitors

Alison Slaughter1, Kellie Jurado2, Lei Feng3, Nanjie Deng4, Nivedita Jena5, Jacques J. Kessl6, James R. Fuchs7, Ronald M. Levy8, Alan Engelman9, Mamuka Kvaratskhelia10
1Ohio State University, Columbus, OH, United States, 2Harvard University, Boston, MA, United States, 3Temple University, Philadelphia, PA, United States

**Background:** Allosteric HIV-1 integrase (IN) inhibitors (ALLINIs) are an important new class of HIV-1 inhibitors. ALLINIs bind at the IN catalytic core domain (CCD) dimer interface in the LEDGF/p75 binding pocket. Consequently, they inhibit HIV-1 IN interaction with its cellular cofactor LEDGF/p75 as well as promote aberrant IN multimerization. Selection of viral strains emerging under ALLINI pressure has revealed mutations at the IN dimer interface near the inhibitor binding site. Here we have investigated A124D and H171T IN substitutions that confer resistance to potent ALLINI BI-D.

**Methodology:** We used biochemical, x-ray crystallography and virology methods to understand the mechanisms for IN H171T and A124D resistance to ALLINI BI-D. Specifically, we utilized size exclusion chromatography (SEC) and dynamic light scattering (DLS) to monitor BI-D induced aberrant multimerization of IN. Homogeneous-time resolved fluorescence (HTRF)-based assays were used to determine the potency of BI-D for inhibiting IN-LEDGF/p75 interactions. Furthermore, we have solved the x-ray crystal structure of BI-D bound to HIV-1 IN CCD containing the H171T substitution. Additionally, binding free energy calculations were performed on complexes of BI-D and IN(WT and H171T).

**Results:** Viruses containing the A124D or H171T mutations in IN are significantly resistant to BI-D treatment in infected cells. SEC and DLS analysis of BI-D interactions with purified mutant INs revealed differing mechanisms of resistance with respect to aberrant multimerization. BI-D treatment promoted higher order oligomerization of WT and H171T IN, whereas the compound did not significantly affect A124D IN. However, H171T IN exhibited significantly reduced binding affinity with LEDGF/p75, whereas WT and the A124D IN bound LEDGF/p75 with similar affinities. Furthermore, x-ray crystallography and binding free energy calculations have revealed the importance of the doubly protonated form and the Nd-protonated tautomers states of H171 for binding BI-D and LEDGF/p75.

**Conclusions:** ALLINI BI-D resistance IN mutations H171T and A124D underscore the inhibitors bimodal mechanism of action. A124D IN overcomes BI-D inhibition by avoiding BI-D induced aberrant multimerization, while the H171T substitution adversely affects BI-D binding to HIV-1 IN and concomitantly affects IN-LEDGF/p75 binding.
Impact of CD4 Mimetics-Resistant Mutations On Susceptibilities To Anti-Env nMAbs
Shigeo Harada1, Samatchaya Boonchawalit1, 2, Tetsuo Narumi3, Hirokazu Tamamura1, Shuzo Matsushita1, Kazuhiro Yoshimura1
1AIDS Research Center, National Institute of Infectious Diseases, Shinjuku, Tokyo, Japan, 2Kumamoto University, Kumamoto, Japan, 3Tokyo Medical and Dental University, Tokyo, Japan

Background: CD4 mimic small compounds (CD4MCs), NBD-556 and its analogues inhibit the gp120-CD4 interaction and can also induce conformational changes in the gp120 architecture thereby exposing masked epitopes of neutralizing antibodies on the Env protein. In this study, we induced the CD4MCs resistant variants using primary isolate to elucidate the interactions between gp120 and CD4MCs, and also investigated the phenotypic change in the CD4MCs resistant isolates against other entry inhibitor and anti-Env neutralizing monoclonal antibodies (nMAbs).

Methodology: To induce resistant variants against five CD4MCs (NBD-556, YYA-021, HAR1-71, JRC-II-191 and HAR4-31) in vitro, we exposed PM1 cells to the bulked and cloned primary KP-5P virus (subtype B, R5). We constructed infectious clones with CD4MC-resistant mutation following in vitro selection. The susceptibility of mutated Env/NL4-3 infectious clones to a CCR5 inhibitor (maraviroc, MVC), 3D6 (anti-CD4bs) and 4E9C (anti-CD4i epitope) were evaluated using single-round assay in TZM-bl cells.

Results: V255M was most frequent mutation in six of ten CD4MC resistant viruses, while T375I mutation was most frequent in three of ten CD4MC resistant viruses. M426I was observed as a major clone in only YYA-021 resistant virus using the bulked virus. To investigate a relationship between the resistant mutations in gp120 and sensitivity to CD4MCs, we constructed Env-mutant clones carrying a single mutation within the KP-5P gp160 backbone, and determined the sensitivity of each clone to CD4MCs. The three mutations, V255, T375 and M426 were associated with high level of resistance to all CD4MCs tested. Furthermore, we examined susceptibilities of the mutated clones to CCR5 inhibitor MVC, CD4bs nMAb 3D6 and CD4i nMAb 4E9C. In this assay in TZM-bl cells, there was no substantial difference between the wild type and CD4MCs resistant clones in sensitivity of MVC. The clones containing V255M or M426I substitutions became relatively resistant to 4E9C compared to the wild type clone, whereas the clone with T375I showed low sensitivity to both 3D6 and 4E9C nMAbs. This finding suggests that the T375I mutation can negatively affect the neutralizing activity of CD4bs and CD4i nMAbs for inducing the conformational change in the Env more than V255I and M426I mutations.

Conclusions: V255M, T375I and M426I, which are located inside of the Phe43-cavity are key mutations for acquiring highly resistant ability to CD4MCs. In these mutations, T375I may contribute to the closing of neutralizing antibody epitopes for CD4i and CD4bs nMAbs.

M184I and M230I Minority Variants in ART-Naïve Patients Are Linked To APOBEC3G/F Activity
Marc Noguera-Julian1, Alessandro Cozzi-Lepri3, Francesca di Giallonardo2, Rob Schuurman4, Martin Daümer5, Huldrych F. Günthard3, Françoise Brun-Vezinet6, Roger Paredes1, Karin J. Metzner3, CHAIN Minority HIV-1 Variants Working Group, 1IrsiCaixa Retrovirology Lab, Badalona, Spain, 2University College, London, United Kingdom, 3Division of Infectious Diseases and Hospital Epidemiology, University Hospital Zurich, Zurich, Switzerland, 4Utrecht Medical Centre, Utrecht, Netherlands, 5Institut für Immunologie und Genetik, Kaiserslautern, Germany, 6Association de Recherche en Virologie et Hematologie, Paris, France

Background: In a recent multicohort European case-control study in ART-naïve patients, presence of at least 1 IAS-2013 RT minority variant (MV) was associated to an increased risk of first-line NNRTI-containing treatment failure. Most prevalent MVs detected were V90I(4%), V106I(3%), V108I(3%), M184I(3%), M230I(2%) and all corresponding to G-to-A mutations. We evaluated whether these mutations could result from APOBEC3G/F activity on the viral genome.

Methodology: ART-naïve HIV-1 infected subjects with no NNRTI resistance by bulk genotyping subsequently undergoing NNRTI containing antiretroviral treatment were selected from 6 European Cohorts. Sequencing of RT was performed using 3 amplicons from the 454 Life Sciences/Roche HIV-1 drug resistance prototype assay plus an additional amplicon for robustness. AVA software (v2.7) was used to obtain error-corrected sequences from which all polymorphisms relative to HXB2 were identified. Then, consensus references were obtained for each sample and sequence data were re-aligned against such consensus using MosaikAligner. These alignments were used to screen for G-to-A nucleotide mutations. GRD-to-ARD sequence contexts were used as APOBEC target sites, while G(YN|RC)-to-A(YN|RC) served as control sites. A Fisher test was run for each sequence to define APOBEC3G/F edition status. All sequences were then pooled and co-occurrence of each of the polymorphisms and APOBEC3G/F edition was tested for significance (Fisher Test, p<0.05).

Results: 353 subjects were included in the study. 326 (93%) samples provided sequence data suitable for analysis for 1 or more amplicon. Of these, 245(75%) and 71(22%) were subtype B and non-B, respectively, while 10(3%) were of unknown subtype. APOBEC3G/F signals were detected in 32 patients. In 8 of them, APOBEC3G/F edited sequences accounted for more of 1% of each sample sequence. M184I and M230I corresponded to APOBEC3G/F mutation patterns while V108I, V90I and V106I did not. Global analysis at the sequence level, separately for each amplicon, showed significant (p<0.05) co-occurrence of APOBEC3G/F edited sequences with M184I, M230I, but not with V90I, V108I and V106I mutations. Stop codons were found in many, but not all, of APOBEC3G/F edited sequences.

Conclusions: M184I and M230I mutations were predominantly found in APOBEC3G/F edited sequences in ART-naïve patients. This suggests that APOBEC3G/F are modulators of viral diversity in vivo to a larger extent than previously expected.
Characterising the Complex Mutational Pathways Associated With Maraviroc-Resistant HIV-1

Xiaowei Jiang1, Felix Feyertag2, Conor Meehan3, Simon Travers4, Charles Craig5, Mike Westby6, Marilyn Lewis1, David L. Robertson1

1Department of Genetics, University of Cambridge, Cambridge, United Kingdom, 2Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom, 3National University of Ireland Galway, Galway, Ireland, 4South African National Bioinformatics Institute, Bellville, South Africa, 5The Research Network, Sandwich, United Kingdom, 6Pfizer R&D, Sandwich, United Kingdom

Background: The drug maraviroc differs from other HIV-1 drugs as it binds the host cell coreceptor CCR5 as opposed to a virus protein. Lack of sensitivity to such entry-inhibitor drugs occurs primarily through emergence of pre-existing viruses that use the CXCR4 coreceptor, while genuine CCR5-antagonist resistance occurs through virus use of the drug-bound CCR5 coreceptor. The aim of this project is to understand the R5 resistance pathway in a comprehensive way based on envelope sequence data.

Methodology: We use population genetic, coevolutionary, recombination, positive selection and structural analysis to analyse the envelope protein sequences from 20 patients from the clinical trials MOTIVATE 1 and 2. All these patients have exclusively CCR5-using (R5) virus. All patients have two groups of sequences that have been sequenced before and after treatment with maraviroc/placebo-arm. Three patients under placebo-arm treatment are used as control.

Results: We find the resistant viral population to be phylogenetically distinct from those susceptible to the drug and associated with a clear genetic bottleneck in each patient, consistent with de novo emergence of resistance. We find limited overlap in the envelope sites or point mutations involved. Particularly, we find: (1) complex coevolutionary networks (indicating epistatic interactions in the context of protein structure) in both the sensitive and resistant populations. (2) A subset of coevolving sites are under positive selection indicating their importance for drug resistance. (3) CD4 binding sites formed a unique coevolutionary network that is independent of the V3 loop. (4) The coevolutionary network formed between the V3 loop and other regions of gp120 and gp41 intersects with sites involved in the N-linked glycosylation motif. (5) Key residues in the signal peptide involved in Env function and expression level coevolve with the potential N-linked glycosylation sequence motifs (NXS/TX). (6) Finally, there is no statistically significant change of the V3 loop structural disorder between sensitive and resistant R5 virus. This indicates changes in other protein regions are required for achieving the binding specificity required for resistant R5 virus, which is consistent with the results of the above coevolutionary analysis.

Conclusions: Coevolution between V3 loop, N-linked glycosylation motifs and the signal peptide are key to V3/gp120/gp41 folding into particular conformations that can utilize drug-bound CCR5 for cell entry. Collectively our results demonstrate that although each viral population’s resistance pathway is context dependent, the evolutionary trajectories of the viruses are significantly constrained accounting for the low levels of resistant R5 virus.

Impact of Minority Drug-Resistant and X4 Variants in Naïve Patients Starting ART With <100 CD4+/mm3

Maria Casadellà1, Christian Manzardo2, Susana Pérez-Álvarez2, Daniel Podzamczer3, Pere Domingo2, Christian Pou1, Marc Noguera-Julian1, Josep M. Gatell2, Josep M. Miro1, Roger Paredes1,1

1IrsiCaixa AIDS Research Institute, Universitat Autònoma de Barcelona, Badalona, Spain, 2Hospital Clínic-IDIBAPS, University of Barcelona, Barcelona, Spain, 3Hospital Bellvitge-IDIBELL, University of Barcelona, Barcelona, Spain, 4Hospital de Sant Pau, Universitat Autònoma de Barcelona, Barcelona, Spain, 5HIV Unit, Hospital Universitari Germans Trias i Pujol, Universitat Autònoma de Barcelona, Badalona, Spain

Background: HIV-1-infected subjects initiating first-line antiretroviral therapy (ART) with CD4+ counts <100 c/mm3 are at increased risk for developing virological failure (VF), opportunistic diseases and death. The impact of drug-resistant minority variants (DRMV) and HIV-1 tropism on the efficacy of first-line ART in this very advanced population is unknown.

Methodology: This was a post hoc analysis from 2 open-label, prospective, randomized clinical trials comparing the efficacy of first-line ART with efavirenz (EFV) vs. lopinavir/ritonavir (LPV/r) + Truvada® (ADVANZ-3 study). Subjects were ART-naïve, had CD4+ counts <100 c/mm3 and wildtype HIV-1 by bulk sequencing at study entry. Stored pre-ART samples were reanalysed for the presence of DRMVs and X4 HIV-1 using 454 sequencing. The detection threshold for DRMVs was 1%; X4 HIV-1 was defined as ≥2% variants with a Geno2Pheno FPR ≤2%. VF was defined as 2 consecutive VL ≥200 c/mL or one VL ≥1000 c/mL at or after month 6 of ART. The different study arms were combined in 2 groups: those starting EFV (EFV group) and those starting a PI/r regimen (PI/r group). DRMVs were defined according to the IAS-USA 2013 list. Only DRMVs conferring resistance to ARV classes included in the regimen started (Tx-DRMVs), i.e. NRTI and NNRTI for the EFV group and NRTI and PI for the PI/r group were considered for the VF analyses. 2-tailed Fisher exact tests and Kaplan-Meier analyses were used to evaluate associations between pre-existing Tx-DRMV or X4 HIV-1 with VF.

Results: The combined dataset included 145 evaluable subjects; 59 received EFV and 86 PI/r therapy (29 ATV/r, 28 IDV/r and 29 LPV/r). Median (IQR) pre-ART CD4+ counts and VL were 39 (20; 60) cells/mm3 and 257,424 (69,192; 500,001) c/mL, respectively. 52 (36%) subjects had X4 HIV-1; 60 (41%) had DRMVs detected. Presence of Tx-DRMV was associated with an increased risk of VF when considering all subjects [Hazard Ratio (HR)=2.0 (95CI: 1.0-4.3), p=0.049] and those starting EFV [HR=4.8 (95CI:1.0-24.6), p=0.031], but not in those initiating PI/r [HR=1.15 (95CI:0.4-3.9), p=0.795]. Similar associations were observed in the Kaplan-Meier analyses. HIV-1 tropism was not associated with VF in any analysis.

Conclusions: Detection of pre-existing DRMVs is helpful to select optimal first-line ART in subjects with <100 CD4+/mm3. X4 tropism was not associated with an increased risk of VF in this study.
604 Retention and Decay of HIV-1 Drug Resistance Mutations in Proviral DNA

Justin De La Cruz1, Saran Vardhanabhuti2, Robert M. Rowner1, Benjamin Pinsky3, Ronald Bosch2, David Katzanstein4

1Medicine, Infectious Diseases, Stanford University, Stanford, CA, United States, 2Biostatistics, Harvard University, Cambridge, MA, United States, 3Pathology, Stanford University, Stanford, CA, United States

Background: The persistence of HIV-1 drug resistant mutations (DRM) in the reservoir of integrated, latent provirus and their fixation and decay rate over time may impact future treatment options. The retention of K103N and other DRM in subjects who failed an Efavirenz (EFV)-based regimen were assessed after suppression to <50 copies/mL for 2-11 years on a protease inhibitor (PI)-based regimen. PBMC proviral DNA was genotyped to determine the kinetics of retention and decay of K103N and other DRM.

Methodology: Proviral DNA was isolated from peripheral blood mononuclear cells (PBMC) of 28 subjects from ACTG 364 and ACTG 5095 with documented K103N in plasma viral RNA at time of EFV failure. HIV-1 pol was amplified and subjected to population sequencing. For most samples, genotypes were obtained at three time points (first suppression (t1), most recent suppression (t3), and between first and most recent suppression (t2)). Repeated measures logistic regression (generalized estimating equations) was used to identify factors associated with detectable K103N in proviral DNA.

Results: At t1, t2, and t3, 50% (14/28), 62% (13/21) and 48% (11/23) of subjects had detectable proviral K103N with median 0.6 (Q1-Q3: 0.6-0.7), 2.6 (1.8-4.0) and 4.2 (2.5-7.1) years of suppression. Years since suppression was not associated with the likelihood of detectable proviral K103N (P=0.53). In adjusted model with years since suppression, log10 plasma HIV RNA level at EFV failure was associated with increased likelihood of observing proviral K103N (P=0.04); odds of detectable proviral K103N was 2.6 (95% CI: 1.0-6.4) times higher per log10 higher HIV RNA at EFV failure. Other covariates (protocol study, age, CD4 count and HIV RNA at baseline) were not associated with detectable proviral K103N. Frequency of NRTI mutations was 75% (21/28) in RNA at EFV failure, 54% (15/28) in DNA at t1, 48% (10/21) at t2, and 39% (9/23) at t3. Detection of nucleoside reverse transcriptase inhibitor (NRTI) mutations in DNA decreased with time on suppression (P<0.01).

Conclusions: K103N in plasma was subsequently identified in the proviral DNA of ~50% of subjects for up to 11 years during PI-based suppression. These results imply seeding of the HIV reservoir during viral failure and confirm the stability of drug resistance in HIV reservoirs during long-term suppressive ART among at least 50%. In those with undetected proviral resistance by population sequencing, persistent drug resistance can exist at lower levels and be clinically relevant.
Prevalence of Minority Resistant Variants To ETR, DRV, and RAL at Baseline in the ANRS 139 TRIO Trial

1Laboratoire de Virologie, Hôpital Bichat-Claude Bernard, Paris, France, 2iAME-UMR 1137, Université Paris 7, Paris, France, 3BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 4Laboratoire de Virologie, Hôpital Henri Mondor, Créteil, France, 5CMG-EC de l’INSERM U897, Université Bordeaux Segalen, Bordeaux, France, 6Service de Maladies Infectieuses et Tropicales, Hôpital St Louis, Paris, France, 7Service de Maladies Infectieuses et Tropicales, Hôpital Pitié-Salpêtrière, Paris, France

Background: ANRS 139 TRIO trial was a 96-week phase II non-comparative trial that evaluated the raltegravir (RAL), etravirine (ETR) and darunavir/r (DRV) combination in highly-experienced patients harboring multi-resistant viruses. 87% of the patients of the trial also received a NRTI- and/or ENF-containing OBT regimen. A high level of virological suppression was observed with 93% of patients with viral load (VL) <50 c/mL at W48, and 88% at W96. The aim of this sub-study was to investigate the prevalence of minority resistant variants (MRV) at baseline (BL) in ANRS 139 TRIO trial.

Methodology: Bulk sequencing at baseline of reverse transcriptase (RT), protease (PR), and integrase (IN) regions was performed and sequences were interpreted according to the ANRS procedures described at www.hivfrenchresistance.org. MRV were assessed using both MiSeq and 454 technologies, with an arbitrarily assigned limit of detection of 1%.

Results: Among the 103 patients included, BL median VL was 4.2 log10 c/mL (IQR = 3.6-4.6). BL bulk sequencing showed a median number of major PI, NNRTI and NRTI resistance-associated mutations (RAM) of 4, 1, and 6, respectively. However, all patients exhibited viruses susceptible to all 3 drugs of the regimen. Deep sequencing was available in 73, 46 and 87 samples for RT, PR and IN regions, respectively. MRV exhibiting at least 1 ETR RAM were detected in 27 patients (37%). Median proportion of ETR MRV was 4.4% (IQR = 2.0%-7.9%). MRV exhibiting at least 1 DRV RAM were detected in 12 patients (26%) with the median proportion of 6.2% (IQR = 2%-10%). Considering the presence of 23 (32%) and 16 (39%) patients exhibited plasma virus resistant to ETR and DRV, respectively. Regarding IN region, MRV exhibiting at least 1 RAL RAM were detected in 6 patients (7%). Among them, 5 exhibited Q148K-mutated MRV with a proportion between 1 and 2%. No patients exhibited MRV to all 3 drugs of interest. During trial follow-up (W96), 19 patients exhibited virological failure (VF). Prevalence of baseline ETR/DRV/RAL MRV according to the virological outcome is depicted in the table below.

Conclusions: In these highly pre-treated patients, but naïve to IN inhibitors, MRV to ETR, DRV, and RAL were detected in 37%, 26% and 7% of patients. The frequency of patients with baseline MRV was not higher in patients experiencing VF when compared to those in success. Further analysis of this dataset should help determine what role, if any, the level of detection of MRV can play in resistance assessments.

Pan Degenerate Amplification and Adaptation for Highly Sensitive Detection of ARV Drug Resistance

Iain J. MacLeod, Christopher F. Rowley, M. Essex.

1Department of Immunology and Infectious Diseases, Harvard School of Public Health, Boston, MA, United States, 2Botswana-Harvard AIDS Institute, Gaborone, Botswana, 3Beth Israel Deaconess Medical Center, Boston, MA, United States

Background: Current drug resistance detection assays are unable to rapidly detect low-level, clinically relevant variants. Molecular probes, such as TaqMan-MGB, can distinguish a single nucleotide polymorphism (SNP) of interest but with the caveat that probes are sensitive to secondary polymorphisms (i.e. non-drug resistance) in the probe-binding region. The highly polymorphic nature of HIV results in the accumulation of secondary polymorphisms that abrogate probe hybridization resulting in a failure to detect drug resistance.

Methodology: Pan Degenerate Amplification and Adaptation (PANDAA) allows fluorescent probes to detect multiple drug resistance mutations by quantitative PCR. Probes to differentiate the K65R, K103N, and G190S/A wild-type and drug resistance SNPs were designed to match the majority consensus from >5,000 HIV-1 Group M sequences. Synthetic constructs of the most prevalent and most divergent probe-binding regions for K65R, K103N, and G190S/A were used to determine assay sensitivity (Figure 1). PANDAA was compared to in-house population genotyping of 30 HIV-1 subtype C-infected patients from Botswana with detectable viral load 6 months after initiating TDF/FTC/EFZ, and 77 ARV-naive patients from Tanzania infected with either subtype A, C, D, or a CRF.

Results: PANDAA was sensitive to 10 copies/reaction using templates containing multiple secondary polymorphisms, and was able to successfully differentiate between wild-type and drug resistance polymorphisms in genetically diverse populations. Drug resistance could be detected at ~1% of a mixed virus population at 1,000 copies total viral RNA, with increasing sensitivity at higher viral loads. PANDAA quantitatively confirmed patient genotyping results obtained using population sequencing, with results obtained in an average of two hours after viral RNA purification.
Conclusions: By removing secondary polymorphisms, PANDAA successfully detected drug resistance in the most genetically divergent samples. We have developed a fast and inexpensive method that is easily adapted to allow accurate quantitation of numerous drug resistance polymorphisms, even when present at very low levels.

607 Genotypic Tropism Testing of Proviral DNA To Guide Maraviroc Initiation in Aviremic Subjects

Federico García1, Eva Poveda1, María Ángeles Ribas1, María Jesús Pérez-Elias4, Onofre J Martínez-Madrid5, Jordi Navarro5, Antonio Ocampo5, Félix Gutíerrez5, Miguel García-Deltoro5, Roger Paredes10, PROTEST Study Group

1Hospital Universitario San Cecilio, Granada, Spain, 2INIBIC-Complejo Hospitalario Universitario de A Coruña, A Coruña, Spain, 3Hospital Son Espases, Palma de Mallorca, Spain, 4Hospital Ramón y Cajal, Madrid, Spain, 5Hospital General Universitario Santa Lucía, Cartagena, Spain, 6Hospital Universitari Vall d’Hebron, Barcelona, Spain, 7Hospital Xeral de Vigo, Vigo, Spain, 8Hospital de Écija, Écija, Spain, 9Hospital General Universitario de Valencia, Valencia, Spain, 10Hospital Universitari Germans Trias y Pujol, Badalona, Spain

Background: Maraviroc (MVC) is a suitable drug for aviremic subjects on antiretroviral treatment (ART) developing toxicity, but its prescription requires prior tropism testing. It is unknown if proviral DNA genotypic tropism testing is reliable to guide MVC initiation in aviremic subjects.

Methodology: This was a Phase 4, prospective, single-arm study (ID: NCT01378910) in 24 HIV care centers in Spain. Participants were MVC-naïve HIV-1-infected adults with HIV-1 RNA (VL) <50 c/mL on stable ART during the previous 6 months, requiring an ART change due to toxicity, with no antiretroviral resistance to the ART started and R5 HIV by proviral DNA genotypic tropism testing (defined as a Geno2Pheno FPR>10% in a singleton). Subjects fulfilling the inclusion criteria initiated MVC with 2 NRTIs, and were followed for 48 weeks. Virological failure was defined as 2 consecutive VL>50 c/mL. Here, we present a pre-specified interim virological safety analysis performed when at least 2/3 subjects reached week 24 of follow-up. Recent adherence was calculated as: (# pills taken/# pills prescribed during the previous week)*100.

Results: Out of 142 subjects screened, tropism results were available from 134: 46 (34%) were X4 and 88 (66%) R5. 74/88 (85%) subjects were included and switched to MVC +2 NRTIs, and 61/74 (82%) had reached week 24 when this analysis was performed. Of these, 20% were women, 31% MSM, 36% had CDC category C, 36% were HCV+ and 10% HBV+. Previous ART included PIs in 33 (55%) subjects, NRTIasi in 26 (43%) and INIis in 1 (2%). Reasons for treatment change were dyslipidemia in 21 (34%) subjects, gastrointestinal symptoms in 11 (18%), psychiatric symptoms in 3 (5%) and "other" in 9 (16%). Median CD4+ counts were 616 cells/mm3 at screening and median nadir CD4+ counts were 143 cells/mm3. MVC was given alongside TDF/FTC in 32 (52%) subjects, ABC/3TC in 26 (43%), AZT/3TC in 2 (3%) and ABC/TDF in 1 (2%). 51 (84%) subjects maintained VL<50 c/mL through week 24, whereas 10 (16%) discontinued treatment: 2 (3%) withdrew informed consent, 1 (2%) was lost to follow-up, 2 (3%) died due to non-study-related causes (1 myocardial infarction at week 0 and 1 lung cancer at week 36), and 4 (6%) developed virological failure (Table).
Conclusions: In this interim 24-week virological safety analysis, initiation of MVC plus 2 NRTIs in aviremic subjects based on genotypic tropism testing of proviral HIV-1 DNA was associated with low rates of virological failure up to week 24.

| Characteristics of subjects developing virological failure (VF) |
|------------------|----------------|----------------|----------------|----------------|----------------|----------------|
| Subject | ART | Week of VF | HIV-1 RNA at VF (c/mL) | Tropism at VF | Recent adherence at VF (Geno2Pheno FPR, %) | Resistance mutations at VF (IAS-USA 2013) | Salvage ART | Regained VL <50c/mL with salvage ART |

608 **Characterization of NNRTI Mutations in HIV-1 RT Using Single Molecule, Real-Time SMRT™ Sequencing**

**Anand Sethuraman**, Michael P. S. Brown1, Colleen Ludka1, Yan Guo1, Ellen E. Paxinos1

1Applications and Collaborations, Pacific Biosciences, Menlo Park, CA, United States; 2Bioinformatics, Pacific Biosciences, Menlo Park, CA, United States

**Background:** Genotypic testing of chronic viral infections is an important part of patient therapy and requires assays capable of detecting the entire spectrum of viral mutations. Single Molecule, Real-Time (SMRT) sequencing offers several advantages to other sequencing technologies, including superior resolution of mixed populations and long read lengths capable of spanning entire viral protein coding regions. We examined detection sensitivity of SMRT sequencing using a mixture of HIV-1 RT gene coding regions containing single NNRTI mutations.

**Methodology:** SMRTbell templates were prepared from PCR products generated from a prospective reference material being developed by BC Center of Excellence for HIV/AIDS, and contained a mixture of fifteen infectious viruses containing single NNRTI resistance mutations (viz V90I, K101E, K103N, V108I, E138A/G/K/Q, V179D, Y181C, Y188C, G190A/S, M230L and P236L) built upon the HIV-1 LAI molecular clone. Templates were sequenced on the PacBio RS II to obtain single molecule long reads using P4/C2 chemistry, using 180 minute movie collection without stage start. The relative abundances of the mutant viruses were then estimated using codon-aware analysis methods.

**Results:** Sequencing of these templates produced average readlengths of 5.0 KB, comprising 40,000-fold coverage across the entire amplicon per SMRT cell. All the expected mutations in the mixture of mutant viruses were accurately identified. Frequencies of NNRTI variants estimated ranged from 0.5% to 12.5%.

**Conclusions:** Codon analysis revealed a number of variants across the amplicon with highly consistent results across SMRT cells. From a single SMRT cell, variants were accurately and reliably detected down to 0.5% with simple analyses. Long polymerase reads and high accuracy reads make it possible to call variants from just a few molecules. SMRT sequencing can identify species comprising a mixed viral population, with granularity and low cost of consumables allowing for smaller multiplexing of samples and first-in-first-out processing.

609 **Celera RUO Integrase Resistance Assay Performs Well Across Several Subtypes**

**Carole L. Wallis**, Raquel V. Viana1, Elias Konstantine Halvas2, John W. Mellors2

1Molecular Pathology, Lancer Laboratories, Johannesburg, South Africa, 2Division of Infectious Diseases, University of Pittsburgh, Pittsburgh, PA, United States

**Background:** Sequence variation is a major obstacle to developing molecular based assays for multiple subtypes. This study sought to independently assess performance characteristics of the ViroSeq™ HIV-1 Integrase RUO Genotyping Kit (Celera, US) for samples of multiple different subtypes.

**Methodology:** 157 samples were used in the validation, 105 from integrase inhibitor naive patients’ plasma samples sent for routine HIV-1 drug resistance testing after failing a 1st- or 2nd-line regimen, and 52 from an external virology quality assurance program (VQA). 15 identical VQA samples were tested in two different laboratories to assess assay reproducibility. Viral RNA was extracted using the ViroSeq extraction module and reverse transcribed and amplified in a one-step reaction. Four sequencing primers were used to span codons 1-288 of integrase. The Rega subtyping tool was used for subtype assignment. Integrase polymorphisms and mutations were determined as differences from the HXB2 sequence and the Stanford database, respectively. Sequences obtained from the two laboratories were aligned and sequence homology determined.

**Results:** HIV-1 RNA in the 157 samples ranged from 3.15 to 6.74 log copies/ml. Successful amplification was obtained for 95% of samples (n=149). The 8 samples that failed to amplify were subtype D (n=3), subtype C (n=1), CRF02_AE (n=1), subtype A (n=2), and unassigned subtype (n=1). Of the 149 successfully amplified samples, 126 (79%) were successfully sequenced with bidirectional coverage. Of the 23 unsuccessful samples, 12 (8%) failed sequencing and 11 (7%) did not have full bidirectional sequence. A result of failure of sequencing primers Primer A (n=1); Primer B (n=4); Primer C (n=2) and Primer D (n=6). For the 15 VQA samples that were sequenced in the two different laboratories, homology of the sequences obtained ranged from 99.01% to 100%. However, Lab 2 detected 23 mixtures; whereas Lab 1 only detected 9 mixtures in the 11219 nucleotide analysed, possibly due to differences between the labs in the methods of sequence analysis. Mutations associated with integrase resistance were observed in seven of the 137 (5%) samples [Q148K; E138K; G140A (n=1)], T97A (n=2), L74I (n=4). Of the four samples with L74I, 3 were subtype G.

**610 Feasibility and Clinical Utility of HIV-1 Genotype Testing in the Setting of Low-Level Viremia**

**Maria Mercedes Santoro**, Daniela Armenia, Claudia Atteni, Lavinia Fabeni, Domenico Di Pinto, Federica Forbici, Ada Bertoli, Caterina Gori, Andrea Antinori, Carlo Federico Perno

1University of Rome Tor Vergata, Rome, Italy; 2L Spallanzani Hospital, Rome, Italy; 3University Hospital Tor Vergata, Rome, Italy

**Background:** We evaluated reliability and clinical usefulness of genotypic resistance testing (GRT), in patients failing combination antiretroviral therapy (cART) with viremia levels 50-1000 copies/mL, for whom GRT is generally not recommended by current guidelines.

**Methodology:** Genotyping success rate (GSR) was evaluated in 12828 HIV-1 plasma samples with viremia >50 copies/mL, tested using the commercial ViroSeq HIV-1 Genotyping System or a homemade system. Samples were stratified in 6 groups according to different viremia levels (50-200; 201-500; 501-1000; 1001-10000; 10001-100000; >100000 copies/mL). Phylogenetic analysis was performed to test the reliability and reproducibility of the GRT at low viremia levels.

Drug-resistance was evaluated in 3895 samples from 2200 treatment failing patients (viremia >50 copies/mL). Multivariable logistic regression analysis was used to evaluate the impact of viremia-levels at genotyping on the prevalence of drug-resistance. Resistance mutations panelled in the IAS list 2013 have been considered.

**Results:** Samples analysed were mainly from patients carrying a subtype B virus (80%), but also from patients carrying non-B subtype viruses (20%), prevalence of the most prevalent ones: CRF02_AG=4.7%; C=4.3%; F=3.3%). Overall, GSR was 96.4% and was independent from subtype. Viremia levels of 50-200 and 201-500 copies/mL afforded GSR of 67.2% and 88.1%, respectively, reaching 93.2% at 501-1000 copies/mL and ≥97.3% above 1000 copies/mL. Phylogenetic analysis revealed a high homology among sequences belonging to the same subject for 96.4% of patients analysed.

The overall drug-resistance prevalence was 74%. Substantial levels of resistance were found also at low viremia levels for all drug classes, with high rates for NRTI and NNNRTI. In particular, detection of any drug-resistance was: 50-200 copies/mL=52.8%; 201-500=70%; 501-1000=74%; 1001-10000=86.1%; 10001-100000=76.7%; >100000=63% (P<0.001).

Multivariable logistic regression confirmed that the risk of having drug-resistance was associated with viremia levels at GRT (P<0.001). The distribution of drug-resistance stratified for viral load was confirmed also considering samples only from patients failing their first-line regimen, though at a lower prevalence was observed (53% vs. 74%). This prevalence was not correlated with pre-therapy viremia (P=0.441).

**Conclusions:** In patients failing cART with viremia levels 50-1000 copies/mL, HIV-1 genotyping provides reliable and reproducible results, that are informative about emerging drug-resistance also at low viremia levels. Results may be helpful for the therapy optimization in patients under virological failure, to decrease the risk of virological failures with drug-resistance accumulation.

---

**611 Tropism Testing by MiSeq Is Comparable To 454-Based Methods But Exhibits Contamination Issues**

BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada

**Background:** Bench-top next-generation sequencing (NGS) has become increasingly popular for HIV applications within the past five years. While "454"-based methods have dominated HIV research, the Illumina MiSeq is gaining popularity based on cost, ease of use, read depth and accuracy through homopolymer regions.

**Methodology:** A total of 514 plasma samples were run on two NGS platforms, and sequencing data from the HIV V3 region were analyzed. Stored first-round PCR products were obtained from the samples which were originally sequenced on a Roche/454 GS-FLX.

The samples underwent further amplification with adaptors appropriate for the Illumina MiSeq. Barcoded samples were sequenced in multiplexed runs of 96 samples on both instruments. Samples were excluded if they had <750 reads by GS-FLX or <10,000 by MiSeq. CXCR4-using tropism was assigned if ≥2% of sequences had a geno2pheno false-positive rate <3.5 - parameters which were previously optimized for the 454, though not the MiSeq.

**Results:** Both platforms were well correlated in terms of the proportion of X4 reads per sample (slope = 0.91, R²=0.90). Median read depth was ~89,000 by MiSeq and ~2500 by GS-FLX. For tropism classifications, the platforms were 89% concordant (459 of 514 samples, Kappa=0.78).

Of the 55 samples with discordant classifications, 62% were X4 by MiSeq but R5 by 454, indicating potential over-sensitivity for minor variants by MiSeq. The median difference in %X4 reads between platforms was 0.2% higher by MiSeq (interquartile range [IQR]: -1.1%-1.3%). Where discordant, samples differed by an absolute value of 2.5% X4 (IQR: 1.3%-8.3%).

We also noted systematic low-level carry-forward contamination on the MiSeq platform: on average, a minimum of 0.04% of the total number of recovered reads (standard deviation 0.02%) were obvious contaminants (non-V3 sequences carried over from previous runs). Contaminant sequences persist in subsequent runs, appearing as many as 7 runs after they were originally processed.
Conclusions: The MiSeq and GS-FLX systems were well correlated with each other and gave similar tropism classifications in 89% of samples. Where discordant, MiSeq tended to call more samples as X4. Laboratories using MiSeq platforms should account for carry-over contamination where possible in their data processing.

612 A Proposed HIV Reference Sample Characterized by Three Next-Generation Sequencing Platforms
Alejandro Gonzalez-Serna1, Chanson J. Brumme1, Winnie Dong1, Eric Cai1, Art F. Y. Poon1, Kelly D. Huber2, Nicolas Sluis-Cremer3, Ellen E. Paxinos4, Luke C. Swenson1, Paul Richard Harrigan1, 5
1British Columbia Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 2School of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 3Medicine, Division of Infectious Diseases, University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 4Applications and Collaborations, Pacific BioSciences, Menlo Park, CA, United States, 5Department of Medicine, Division of AIDS, Vancouver, BC, Canada

Background: “Deep” sequencing allows detection of low frequency minority variants, but establishing the analytical characteristics of such assays, including the error rate and limit of detection, will require repeated sequencing of known reference samples. We present sequencing results from three next-generation platforms for one such potential sample.

Methodology: Fifteen infectious viral clones, each containing a single NNRTI resistance mutation (V90I, K101E, K103N, V108I, E138A/G/K/Q, V179D, Y181C, Y188C, G190A/S, M230L and P236L) were created by site directed mutagenesis of HIV-1LAI. Mutants and wild-type viruses were pooled at equal infectivity into a single sample, “RSVP” (reference sample for validating platforms), which was extracted and subjected to RT-PCR. Two second round PCR amplicons were generated: a 1.8 kb region of pol (HXB2 2469-4295) sequenced on the PacBio® RS (v1), and 339 bp region of RT (HXB2 2813-3151) was sequenced on the Illumina MiSeq (v2 2x250 paired end) and 454 Life Sciences GS-Jr. Cross-platform variation was evaluated including amino acid (aa) frequency of the expected NNRTI mutants and error rates in the region covered by all three platforms (RT codons 96-194). A logistic regression model was used to model the error rates. In addition, serial dilutions of the 1st round PCR product were sequenced by MiSeq.

Results: Approximately 50,000, 185,000, and 3100 sequence reads were obtained for PacBio, MiSeq and 454 respectively. The frequency of minor NNRTI resistance variants detected by the three platforms was similar (see figure). When raw sequences were analyzed (no quality score filtering) marginally higher error rates were observed for PacBio compared to MiSeq and 454. For MiSeq, discarding bases with quality below a specific cutoff (q-score 10, 15, 20, 25) resulted in improved error rates, with q20 balancing a tradeoff between read retention and sequencing accuracy (q20 error rate 1.2%). Sequencing errors in homopolymer-rich regions were frequently observed in 454 sequences, occasionally in PacBio, but rarely in MiSeq. Additionally, MiSeq results were robust to dilution of the 1st round PCR product up to 200,000-fold.

Conclusions: We have characterized the performance of three next-generation sequencing platforms using a proposed HIV reference sample; RSVP is a mixture of protease-RT from 16 HIV-1 variants that we are making available to interested groups to use when validating the detection of minority NNRTI resistant variants.

Cost Effectiveness Studies of ART and Drug Resistance Testing

613 Antiretroviral Switch Strategies for Lowering Costs of Therapy: 48-Week Cost-Efficacy Analysis
Josep M Llibre1, Gloria Cardona2, Jose R Santos3, Angels Andreu4, Xavier Bonafont5, Bonaventura Clotet1
1HIV Unit, University Hospital Germans Trias i Pujol, Badalona, Spain, 2Pharmacy, University Hospital Germans Trias i Pujol, Badalona, Spain, 3University Hospital Germans Trias i Pujol, Badalona, Spain

Background: The economic recession has led to a generalized shortage of investment in public health and the antiretroviral treatment (ART) budget in some European countries. Some ART were proactively switched in selected individuals to generate cost savings. We undertook a complete 48 week cost-efficacy analysis to evaluate this strategy.

Methodology: We defined cost-reduction measures (CRM) as all those switches that aimed to reduce the cost of treatment in patients with virological suppression (HIV-1 RNA <50 c/mL). We registered all treatment changes and a 48 week snapshot analysis (HIV-1 RNA <50 c/mL) was performed. All direct costs were considered: cost of therapy calculated from manufacturer sales price plus 4% VAT, all resource consumption used in the management of toxicity, any treatment change, and therapeutic failure, for which we used the official rates to apply by the hospital.
Results: During the study period, 673 switches were made, of which 378 (56.2%) were CRM (16% of all patients treated), leading to overall savings of €87,410/month. Switching TDF/FTC for ABC/3TC was the most common CRM (129, 31.3%), followed by simplification to PI/r monotherapy (102, 26%). The CRMs that generated the greatest savings were switching to PI/r monotherapy (38%), substitution of raltegravir (24%), switching TDF/FTC for ABC/3TC (13%), and switching to nevirapine (5%). After 48 weeks, 318/378 (84.1%) patients remained on the same treatment, while 60 (15.9%) had changed it. Only in 30 patients (7.9%) the change was related with the prior switch: side effects (22, 5.8%) and virological failure (8, 2.1%). The most common side effect was low-grade gastrointestinal toxicity (diarrhea and abdominal discomfort) by abacavir (2.4%), lopinavir (1.3%), and darunavir (0.5%), followed by rash by nevirapine (1,1%), and central nervous system toxicity by efavirenz (0.5%). Changes unrelated to the switch included adverse events (20, 5.3%), pharmacokinetic interactions (7, 1.9%), treatment withdrawal (2, 0.5%) and simplification (1, 0.26%). All toxicities were grade 1-2. Among 8 virological failures, 4 had been switched to PI/r monotherapy, 3 to triple PI/r, and 1 unboosted ATV. The switch was related to the virological failure in only 1 subject. 375/378 patients had plasma HIV-1 RNA <50c/mL at 48 weeks. During 48 weeks, treatment changes cost €40,124, extra visits 2,553 €, and supplemental tests 2,971 €, therefore generating a final net saving of €922,855.

Conclusions: Proactively switching the ART in properly selected patients with sustained virological suppression generated significant cost savings at 48 weeks and proved to be a cost-effective strategy. These findings might have implications for decision makers in designing safe strategies that maintain HIV-1 suppression at lower costs.

614 The Cost-Effectiveness of Genotype Testing for Primary Resistance in Brazil
Paula M. Luz1, Bethany L. Morris1, Beatriz Grinsztejn1, Kenneth A. Freedberg1, 2, Valdilea G. Veloso1, Rochelle P. Walensky1, 2, Yoriko M. Nakamura1, Paul E. Sax1, 2, Claudio J. Struchiner1, A. David Paltiel7
1Fundação Oswaldo Cruz, Instituto de Pesquisa Clínica Evandro Chagas, Rio de Janeiro, Brazil, 2Massachusetts General Hospital, Medical Practice Evaluation Center, Boston, MA, United States, 3Massachusetts General Hospital, Division of General Medicine, Boston, MA, United States, 4Massachusetts General Hospital, Division of Infectious Disease, Boston, MA, United States, 5Harvard Medical School, Boston, MA, United States, 6Brigham and Women’s Hospital, Division of Infectious Disease, Boston, MA, United States, 7Yale School of Public Health, New Haven, CT, United States

Background: A recent surveillance study in 20 centers from 13 populous cities in Brazil reported a primary NNRTI resistance prevalence of 4.4%. Yet, a policy of universal genotype-resistance testing (GRT) prior to first-line ART initiation is not recommended by the Brazilian National AIDS Program guidelines. We sought to evaluate the cost-effectiveness of such a policy.

Methodology: We used a previously published microsimulation model of HIV disease (CEPAC-International), populated with data from Brazil. We compared the clinical impact, costs, and cost-effectiveness of no initial genotype test to GRT, simulating both patients who did and did not have primary NNRTI resistance, and weighing the results based on primary resistance prevalence. Model parameters were derived from the HIV Clinical Cohort at the Evandro Chagas Clinical Research Institute at the Oswaldo Cruz Foundation and from published official Brazilian Governmental data: 69% were male, mean age 36 years (SD 10 years), mean CD4 348 μL (SD 300/μL), and a genotype cost of 2012 US$233. We assumed annual costs of US$2,200 for 2nd-line ART and US$12,750 to US$23,280 for 3rd- through 5th-line ART; these were varied broadly in sensitivity analyses. Costs were discounted at 3%/year. A strategy was defined as “very cost-effective” (or “cost-effective”) if its incremental cost-effectiveness ratio was less than 1x (or 3x), the 2012 Brazilian per capita GDP of US$12,340.

Figure 1. Multivariate sensitivity analysis varying genotype test cost, subsequent-line ART costs, and primary NNRTI resistance prevalence. The black dot indicates the base case result.
Results: Compared to no initial genotype test, GRT increased discounted life-expectancy from 18.52 to 18.55 years and reduced discounted lifetime cost from US$98,100 to $97,000; thus, in the base case, GRT was cost-saving. GRT was cost-effective at primary resistance prevalences as low as 0.4% and remained cost-effective even when subsequent-line ART costs were assumed to be equal to second-line ART costs (ICER of US$14,290). Cost-inefficient results were observed only when simultaneously holding multiple parameters to extremes of their plausible ranges (Figure 1).

Conclusions: This study is the first to demonstrate the attractiveness of GRT in a middle-income country with free-of-charge access to antiretroviral therapy. The cost of baseline genotype-resistance testing in ART-naïve individuals in Brazil has the potential to improve survival and save money over the lifetime of the patient, as it reduces the need for more costly subsequent-line therapies. Initial genotype-resistance testing should be recommended by the Brazilian National Health System.

HIV Early Detection: Application of New Assays

615 Application of the Geenius™ HIV/1 Supplemental Assay for Detection of Recent HIV Infections
Sheila M. Keating1, 2, Gary Murphy1, Alex Wetter3, Reshma Kassanjee4, David Matten4, Shelley N. Facente1, Mila Lebedeva1, Michael P. Busch1, 2, Christopher D. Pilcher6, Consortium for Evaluation of Performance of HIV Incidence Assays (CEPHIA)
1Blood Systems Research Institute, San Francisco, CA, United States, 2University of California San Francisco, San Francisco, CA, United States, 3Public Health England, London, United Kingdom, 4SACEMA, Stellenbosch, South Africa, 5University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 6Health Strategies Inc, St Paul, MN, United States

Background: Assays that measure evolving biomarkers during HIV seroconversion are being used in cross sectional studies for HIV incidence estimation. The Bio-Rad Geenius™ HIV 1/2 Supplemental Assay has been developed for HIV-1 and HIV-2 antibody (Ab) confirmation and differentiation. It is a rapid (30 minute), immunochromatographic test that utilizes serum, plasma, finger stick or whole blood to detect HIV Ab. Single-use dual-path lateral flow cartridges include HIV-1 (p31, gp160, p24, p41) and HIV-2 (gp36, gp140) antigen bands and a protein A control band bound to the membrane solid phase, and protein A conjugated to colloidal gold dye particles for detection. Band intensities are captured by an automated reader enabling quantification of IgG Ab levels. Previous analysis by Bio-Rad of CEPHIA Developmental and Qualification Panels led to provisional criteria for interpretation of results for HIV incidence applications.

Methodology: Geenius™ assays were performed on the 2500-member CEPHIA Evaluation Panel. This panel consists of clade diverse specimens from 918 individuals from the United States, Brazil and Africa, predominantly ART-naïve, with estimable dates of infection (from 0-12 years), supplemented by “challenge” specimen sets from patients with factors predisposing to false recent results (elite controllers, suppressive ART, and AIDS). A Geenius™ recency index was calculated using HIV-specific band intensities for p31, gp41, and gp160 relative to the control band. Regression and frequency estimation were used to estimate mean duration of recent infection (MDRI: mean time, within 1-year post estimated exposure, that subjects return recent results) and false recent rate (FRR: proportion of recent test results among patients at least 1-year post infection).

Results: Using the manufacturer’s cutoff for recent infection discrimination (index=1.5) the MDRI was calculated to be 157 (140.5-174.7) days. The FRR on eligible specimens was 8.9% [7.3-10.7%]. False recent misclassification was common in specimens from patients on suppressive ART (71.3% [65.7-76.5%]) and from elite controllers (38.7% [28.8-49.4%]), but was uncommon in specimens from patients with AIDS or low CD4 counts (4.8% [2.7-7.9% CI]) and 3.9% [1.8-7.2% CI] respectively). Weighting clinical stages among untreated individuals had no impact.

Conclusions: This is the first evidence that the Geenius™ assay may be used as a method for identifying recent HIV infection. The MDRI and FRR presented here are similar to other currently used methods for recent HIV infection. The rapid test format allows for classification of recent infections at the same time that rapid HIV/1 Ab confirmation and differentiation is performed.

616 Cost Effectiveness of Adding 4th-Generation Immunoassay Screening After a Negative Rapid HIV Test
Angela B. Hutchinson1, Stephanie Cohen2, Emily Westheimer1, Cynthia Gay1, Elliott Morse1, Laura Hall1, Lisa Hightow-Weidman1, Benjamin Tsoi2, Mark Pandori1, Philip J. Peters1
1Centers for Disease Control and Prevention, Atlanta, GA, United States, 2San Francisco Department of Public Health, San Francisco, CA, United States, 3New York City Department of Health and Mental Hygiene, New York, NY, United States, 4University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 5Health Strategies International, Oakland, CA, United States, 6ICF International, Atlanta, GA, United States, 7San Francisco Department of Public Health Laboratory, San Francisco, CA, United States

Background: HIV prevention services in high-risk communities, these assays may not detect early HIV infection. We evaluated the cost-effectiveness of using 4th generation lab-based immunoassay (4G IA) following a negative rapid HIV test to screen for early infection.

Methodology: A published mathematical model was used to estimate HIV transmissions averted and cost per quality-adjusted life years gained (QALYs) attributable to 4G IA screening following rapid testing. HIV transmissions averted due to serostatus awareness and viral load suppression were calculated for a one year period, conservatively assuming infected persons would be diagnosed one year later in the absence of 4G IA screening. Testing outcomes were derived from the STOP study, a multi-site, prospective evaluation of HIV testing methods. Participants from 12 HIV testing sites in sexually transmitted infection clinics and community-based HIV testing programs in New York City, San Francisco, and North Carolina were screened with a point-of-care rapid HIV test. Rapid negative specimens were then tested for early HIV infection with 4G IA (Architect HIV Ag/Ab Combo assay). Specimens with repeatedly reactive 4G IA results were confirmed with Multispot (HIV-1/HIV-2 Rapid Test) and discordant 4G IA/Multispot results were resolved with an HIV-1 nucleic acid amplification test. Key input values included: 80% receipt of test results, 75% uptake of antiretroviral therapy (ART), costs of $11.00 for HIV negative
Results: From September 2011 to July 2013, rapid HIV testing detected infection in 963 (1.35%) of 71,616 participants. Screening of the remaining 70,653 rapid test-negative specimens with 4G IA identified an additional 127 (0.18%) infections, adding $785,700 in testing costs and $2,015,900 in total program costs (including costs for earlier ART initiation). The 4G IA testing resulted in 6.6 HIV transmissions averted, 29.2 QALYs saved, and overall cost-savings. In threshold analysis, the acute HIV positivity rate could drop to 0.13%, at which point the program is no longer cost-saving but would have a cost-effectiveness ratio of $1,900/QALY gained, and to 0.07%, and still remain below the $100,000/QALY threshold. At base case positivity rates, testing costs could increase approximately four-fold and remain below the $100,000/QALY threshold.

Conclusions: Using 4G IA to screen rapid-test negative specimens for early HIV infection can be a cost-effective strategy in populations at high risk for HIV.

617 Performance of HIV Rapid Tests To Identify Seroconverters in MTN 003 (VOICE)

Urvil M. Parikh,1 Edward Livant,1 Cliff Kelly,1 Rashika Maharaj,1 Marshall W. Munjom,1 Patrick Karugaba,1 Natasha Samsunder,2 Rosetta Lindwe Nhlangulela,3 Jeanne Marrazzò,2 Zvavahera M. Chirenje1; on behalf of the VOICE Study Team

1University of Pittsburgh School of Medicine, Division of Infectious Diseases, Pittsburgh, PA, United States, 2Magee-Womens Research Institute & Foundation, University of Pittsburgh Medical Center, Pittsburgh, PA, United States, 3Fred Hutchinson Cancer Research Center/SCHARP, Seattle, WA, United States, 4Medical Research Council of South Africa HIV Prevention Research Unit, Durban, South Africa, 5UQ/UCSF Collaborative Research Programme in Women’s Health, Harare, Zimbabwe, 6Core Laboratory, M-JHU Research Collaboration, Kampala, Uganda, 7Centre for the AIDS Programme of Research in South Africa (CAPRISA), Durban, South Africa, 8Laboratory, Aurum Institute, Klerksdorp, South Africa, 9University of Washington Division of Allergy & Infectious Diseases, Seattle, WA, United States

Background: Accurate and efficient identification of seroconverters in antiretroviral-based HIV prevention trials is critical for minimizing emergence of resistance. The use of second-generation (IgG) HIV-1 rapid tests followed by confirmation by Western blot and/or HIV-1 RNA is the most common strategy to identify seroconverters in HIV prevention studies. We evaluated 150,125 HIV rapid tests performed in MTN 003 (VOICE) to assess the performance of this detection algorithm.

Methodology: VOICE evaluated the safety and effectiveness of oral tenofovir disoproxil fumarate (TDF), oral TDF-emtricitabine and vaginal tenofovir 1% gel for the prevention of HIV infection in 5029 women from 15 clinical sites in South Africa, Uganda and Zimbabwe. Participants underwent monthly HIV testing with one or two concurrent rapid tests including Alere Determine™ HIV-1/2, Orasure Oraquick Advance® Rapid HIV-1/2 and/or Trinity Biotech™ Unigold Recombigen® HIV. Confirmation of infection following a positive rapid test was done using Western blot (WB) (Bio-Rad). HIV RNA PCR (Abbott M2000 or Roche TaqMan) was used to resolve negative or indeterminate WB following one or two positive rapid tests.

Results: Rapid testing correctly identified HIV infection status (positive or negative) at 77,795/77,915 (99.85%) follow-up visits in VOICE. Of the 161 rapid tests from 104 participants at 120 visits where rapid test results were discrepant with WB and/or RNA PCR test results, 51/161(32%) were due to a false positive rapid and 110/161 (68%) were due to a false negative rapid. Of note, 48 false-positive cases had rapid test results for subsequent visits; of these, 14 (29%) cases (from 7 participants) resolved by switching the falsely positive rapid kit to a different rapid kit. The resolution of HIV status after discrepant results took a median of 32 days (IQR 27-48 days). The overall sensitivity for Determine, Unigold and OraQuick was 88.78%, 85.86% and 61.54% respectively, and specificity was 99.96%, 99.97% and 99.99% respectively. The positive predictive values of the tests were 91.75%, 94.89% and 94.12% respectively.

Conclusions: In a diverse clinical trial setting, the combination of Determine, Unigold and Oraquick accurately (99.85%) characterized HIV infection status in VOICE, but had limited sensitivity (61-88%) for identifying acute seroconverters. Resolution of discrepant results prolongs the confirmation of seroconversions. The use of newer antigen/antibody rapid tests could improve current HIV testing algorithms by reducing the time from infection to detection.

618 Algorithms and Acute Infections: Innovations in Routine HIV Screening

Kara I. Geren,1 Eric O. Moore,2 Robert E. Fromm,3 Dan Hobohn,4 Joy Jenkins,1 Heather L. Jordan,1 Frank LoVecchio,5 Nancy Lowman,6 Robert McGuire,6 Cheri K. Tomlinson6

1Emergency Medicine, Maricopa Integrated Health System, Phoenix, AZ, United States, 2Grants Administration, Maricopa Integrated Health System, Phoenix, AZ, United States, 3Administration, Maricopa Integrated Health System, Phoenix, AZ, United States, 4Clinical Laboratory, Maricopa Integrated Health System, Phoenix, AZ, United States, 5Adult Emergency Department, Maricopa Integrated Health System, Phoenix, AZ, United States, 6Information Technology, Maricopa Integrated Health System, Phoenix, AZ, United States

Background: CDC recommends routine, opt-out HIV screening in all healthcare settings if the undiagnosed prevalence is ≥ 0.01%. Acute/Stage 0 HIV infections are defined as a positive initial serologic test, negative or indeterminate supplemental antibody test, and positive HIV RNA test. Acute phase transmission rates are as much as 16 times higher than the overall sexual transmission rate. Early diagnosis of HIV infection results in better health outcomes. Testing for HIV antigens and antibodies using 4th generation technology allows earlier diagnosis of HIV, notably during the acute phase.

Methodology: The Adult Emergency Department (ED) of the Maricopa Integrated Health System (MIHS), a metropolitan safety-net hospital serving predominantly uninsured and minority populations, implemented routine, opt-out HIV screening using 4th generation testing technology. During triage, ED nurses inform patients that all blood draws include an HIV test at no additional cost. Patients are informed of their right to opt-out and ask questions. Consent is inferred unless the patient opts-out or is excluded per MIHS policy. Following a documented, pre-defined department protocol, nurses place an “HIV: If labs drawn” order for which an ED physician consign is required. Notifications of preliminary positive results are completed by the physician and Care Management with transition to a Linkage to Care Specialist upon discharge.

Results: In our first 27 months, MIHS conducted 24,634 tests through the ED. Only 15% of patients actively opted-out of HIV screening. We have confirmed 69 previously undiagnosed cases of HIV infection (0.28% positivity rate). Of those cases, 17 (25%) are acute infections. Initial mean HIV viral load in acute cases is 4,813,837 cpd/ml compared to 403,288 cpd/ml in chronic cases. Latest mean viral load in acute cases is 12,038 cpd/ml with 53%
having achieved viral suppression. Latest mean viral load in chronic cases is 58,977 cpy/ml with 41% having achieved viral suppression. Initial mean CD4 count in acute infections is 554 compared to 280 in chronic cases. Latest mean CD4 count in acute cases is 743 compared to 414 in chronic cases. The mean between ED and first HIV medical appointment is 39 days in acute cases and 51 days in chronic.

**Conclusions:** Our experience confirms that individuals with acute HIV infection often seek medical care for their symptoms presenting opportunities to intervene. In the absence of 4th generation testing technology, one in four diagnosed cases at our ED may have been misclassified as HIV-negative. Because MIHS has routinized testing, notification, and linkage to care activities, we are able to identify previously undiagnosed cases earlier, get them into care sooner, and suppress their viral load faster than more chronic infections.

### 619 Evaluation of the Proposed US CDC Algorithm for Detection of Acute HIV Infection in Serial Samples

**Leigh Anne Eller**, Mark Manak, Ashley Shutt, Rapee Trichavor, Joseph Oundo, Cornelia Lueer, Fatim Jallow, Jerome Kim, Merlin Robb, Sheila Peet

1US Military HIV Research Program, Walter Reed Army Institute of Research/ Henry M. Jackson Foundation, Bethesda, MD, United States, 2AFRIMS, Bangkok, Thailand, 3Walter Reed Project, Kericho, Kenya, Kericho, Kenya, 4Mbeya Medical Research Centre, Mbeya, Tanzania, United Republic of, 5Makerere University Walter Reed Project, Kampala, Uganda, 6US Military HIV Research Program, Walter Reed Army Institute of Research, Silver Spring, MD, United States

**Background:** A new HIV diagnostic algorithm has been proposed by the US CDC to improve acute HIV infection (AHI) detection and type differentiation of anti-HIV-1 from HIV-2 antibodies. The algorithm employs a 4th generation HIV-1/2 ELISA (4th gen) followed by the Multispot HIV-1/HIV-2 Rapid Test and nucleic acid testing, if indicated. We evaluated algorithm performance on well-characterized panels of serial samples collected from AHI cases identified by the Early Capture HIV Cohort (ECHO) Study, RV217.

**Methodology:** Individuals at high risk of HIV infection from Tanzania, Uganda, Kenya and Thailand were screened twice-weekly by Aptima HIV-1 Qualitative RNA assay (Gen-Probe, Inc. San Diego, CA). Following a reactive (R) Aptima result, serial samples collected twice weekly from consenting participants were screened with GS Combo Ag/Ab EIA (4th Gen), GS HIV-1/2 Plus 0 EIA (3th Gen), HIV1/2 Multispot (Bio-Rad Laboratories, Redmond, Washington), HIV-1 p24 Antigen (Ag) Test (Bio-Rad, France) and Abbott m2000 real-time quantitative HIV RNA assay (Des Plaines, Illinois). In this algorithm, an individual is considered HIV uninfected if the 4th gen ELISA is non-reactive (NR), and HIV infected if a R 4th gen ELISA is confirmed by positive (POS) Multispot result. An individual is considered to be an AHI case, if the 4th gen ELISA is R, Multispot is negative, and HIV nucleic acids is detected.

**Results:** Of 29 Acute HIV infection cases, only 7 were R by 4th gen ELISA at the earliest timepoint (median 2 days past R Aptima) with a detectable viral load. HIV-1 viral loads in the very early NR GS Combo samples ranged from 2.16 to 5.95 log10 copies/ml and were on the early viral upslope before peak viremia. In the 22 4th gen NR cases, p24 concentrations were lower than the package insert sensitivity of 50pg/ml. Five of seven (5/7) cases demonstrated R GS Combo results with p24 levels less than 50pg/ml (range 25-49 pg/ml). GS Combo reactivity was detected at a median 7 days (range 2-15) after the first reactive RNA test, 6 days before peak viral load, and 8 days before 3rd gen ELISA reactivity. Multispot reactivity was detected on median day 20. No HIV-2 infections were observed. Using the simulated algorithm, GS Combo reflexing to Multispot, in samples collected within the first 14 days post HIV-1 RNA positivity, 29/29 acute infections with p24 levels above 50pg/ml.

**Conclusions:** The proposed US CDC algorithm identified 29/29 individuals with HIV-1 acute infection. Only 7/29 AHI cases were detected at the first visit when HIV-1 viremia and p24 concentration were low. This algorithm, with the addition of a 4th gen ELISA, enhances AH detection sensitivity. Robust point of care HIV viral load detection would further reduce the diagnostic window, especially when screening most-at-risk cohorts.

### 620 Evaluation of the Hologic Aptima HIV-1 Quant Dx Assay With HIV-1 Subtypes

**Mark M. Manak**, Holly Hack, Tracey Traic, Sangeetha Nair, Andrew Worlock, Sheila A. Peet, Jennifer Malia, Linda Jagodzinski

1DLDM, US Military HIV Research Program, KUH, Silver Spring, MD, United States, 2Hologic, San Diego, CA, United States, 3DLDM, US Military HIV Research Program, WRAIR, Silver Spring, MD, United States

**Background:** An important consideration in selection of HIV-1 viral load assays is the ability to detect and accurately quantify the diversity of current HIV-1 subtypes. In this study, we evaluated the quantitation of HIV-1 subtypes by a new Hologic Aptima HIV-1 Quant Dx Assay, which is currently in development, on the fully automated PANTHER System and compared it to that of the Roche COBAS AmpliPrep/COBAS TaqMan HIV-1 v2.0 and the Abbott m2000 RealTime HIV-1 Assays.

**Methodology:** Assay performance to include precision, linear dynamic range, and lower limit of detection (LLLOD) was evaluated using well-characterized panels of cultured virus spiked into HIV negative plasma. LLOD was determined by testing thirty replicates each of 2-fold serial dilutions of cultured subtype B virus at 100 to 1.5 copies/ml. Subtype sensitivity was evaluated on 62 previously subtype6 plasma samples from Uganda, Kenya, Tanzania and Thailand and 171 HIV-1 isolates from 35 different countries. Samples diluted to -1E5 copies/ml were tested using the Hologic Aptima, Roche TaqMan, and Abbott m2000 quantitative HIV-1 RNA assays.

**Results:** The Aptima assay demonstrated good linearity from 1E2 to 1E7 copies/ml, with R² values >0.992 for all subtypes. Assay accuracy was within 0.15 log of the target value of the secondary HIV-1 WHO standard. Probit analysis of serial dilutions of cultured HIV-1 established a LLOD of 3.1 copies/ml (50%) and 15 copies/ml (95%), with a precision of 10.4% at 100 copies/ml. Quantitation of HIV-1 subtypes by the Hologic assay agreed closely with those by the Roche and Abbott assays, and were within 0.5 logs in 94.8% and 84.9% of the samples, respectively; the remainder within 1 log of the Hologic measurement.
Conclusions: The Hologic Aptima HIV-1 Quant Dx Assay demonstrated excellent specificity, precision, sensitivity, and linear dynamic range. The assay was capable of accurate quantitation of all major HIV-1 subtypes including subtypes A, B, C, D, F, G, H, O, CRF01_AE, CRF02_AG and complex mixtures, with results comparable to that of the Roche TaqMan v2.0 and Abbott m2000 quantitative HIV-1 RNA assays. The fully automated assay is easy to perform, and results for at least 275 samples can be obtained within an 8 hour shift.

CAP/CTM V. 2.0 Using Dried Blood Spots Ineffective at Diagnosing Antiretroviral Treatment Failure
Souleymane Sawadogo1, Andreas Shiningangavwe2, Joy Chang3, Maher Andrew1, Chuntu Yang2, Essigle Gaëb3, Harold Kaura4, Dennis Ellenberger4, David Lowrance1  
1CDC-Namibia, Windhoek, Namibia, 2Namibia Institute of Pathology, Windhoek, Namibia, 3DGHA/CGH/CDC, Atlanta, GA, United States

Background: The 2013 WHO guidelines for antiretroviral treatment (ART) of HIV infections recommend viral load (VL) for routine monitoring and diagnosis of treatment failure (TF) defined as > 1,000 copies/ml. Due to operational simplicity, dried blood spots (DBS) are recommended as an alternative specimen type however at a higher TF diagnostic threshold of 3-5,000 copies/ml. DBS based VL testing has been extensively evaluated in comparison with plasma based testing however performance has varied. We assessed DBS against plasma based VL performance under field laboratory conditions using the Cobas Ampliprep/TaqMan Version 2.0 (CAP/CTM), a common platform for screening for suspected virological TF.

Methodology: EDTA whole blood (WB) specimens were obtained at three health facilities from 823 ART patients after ≥6 months on ART when blood was submitted for routine or targeted plasma VL tests at the Namibia national reference laboratory. DBS were prepared from these blood specimens within 6 hours after blood draws. DBS were dried overnight and packaged according to the WHO recommended method. DBS VL was determined using CAP/CTM HIV-1 version 2.0 test kits following the manufacturer’s instructions. The assay has a lower detection limit of 2.60 log10 copies/ml. DBS VL data were analyzed using plasma VL as reference standard.

Results: Using DBS (n=823) the clinical sensitivity, specificity, positive (PPV) and negative predictive value (NPV) with 95% confidence intervals (CI) were 0.99 (0.96 - 0.99), 0.55 (0.52 - 0.59), 0.33 (0.29 - 0.38) and 0.99 (0.99 - 1.0), respectively, at a threshold of 5,000 copies/ml; and 0.99 (0.97 - 1.0), 0.26 (0.22 - 0.29), 0.29 (0.26 - 0.33) and 0.99 (0.90-1.0), respectively, at a threshold of 1,000 copies/ml. The prevalence (95% CI) of TF was 0.18 (0.16 - 0.21) and 0.23 (0.21 - 0.26) in plasma and 0.55 (0.51 - 0.58) and 0.80 (0.77 - 0.83) in DBS at the 5,000 and 1,000 copies/ml thresholds, respectively.

Conclusions: Low specificity and PPV of the CAP/CTM on DBS at both evaluated threshold levels indicate high rates of false positive results for virological TF may occur if this approach was used for routine ART patient monitoring and TF diagnosis. Even use of the more conservative DBS specific TF threshold of 3-5,000 copies/ml recommended by the 2013 WHO guidelines may result in unnecessary ART regimen changes for patients responding favorably to current treatment. These results add to the published literature highlighting suboptimal specificity and PPV of DBS based VL testing. As such, recommendations for use of DBS for routine VL monitoring may require further evaluation. Additional research is needed to better understand the effectiveness of these approaches in routine programmatic settings, including the performance of other assay versions and types.

Reliable and Accurate CD4 T Cell Count and Percent of the New Portable Flow Cytometer CyFlow MiniPOC
Milena Nasi1, Sara De Biasi1, Elena Bianchini1, Lara Gibellini1, Marcello Pinti1, Tiziana Scacchett1, Tommaso Trenti1, Vanni Borghi2, Cristina Mussini2, Andrea Cossarizza1  
1University of Modena and Reggio Emilia, Modena, Italy; 2Department of Clinical Pathology, NOCSAE Baggiovara, Modena, Italy; 3Infectious Diseases Clinics, Azienda Ospedaliero-Universitaria Policlinico di Modena, Modena, Italy

Background: An accurate, reliable, and affordable CD4 T cells count is essential in several parts of the world. Flow cytometry is the “gold standard” for CD4 T cell count, but this technique is expensive and requires sophisticated equipment and trained personnel. In addition, the lack of ready access to technical support and quality assurance programs limits the use of flow cytometry techniques in resource-constrained countries. Instruments are now available that can solve these problems. We have tested the new portable flow cytometer for CD4+ T cell count percentage, named CyFlow MiniPOC (Partec), and analysed its sensitivity, carry-over contamination and repeatability. Its accuracy has been compared analysing the same blood samples with 2 other systems based upon CyFlow Counter (Partec) or Cytomix FC 500 (Beckman Coulter), and analysed its sensitivity, carry-over contamination and repeatability. Its accuracy has been compared analysing the same blood samples with 2 other systems based upon CyFlow Counter (Partec) or Cytomix FC 500 (Beckman Coulter).

Methodology: Venous blood from 59 adult HIV-1+ patients (age: 25-58 years; sex: 43 males; CD4 count: 34-1,115 cells/ul; CD4%: 3.1-48.0) was collected in EDTA blood, stained with the Partec MiniPOC CD4% count kit - dry kit, and analysed within a maximum of 2 hours. CD4 T cell count and percentage were determined by the CyFlow MiniPOC instrument, equipped with a 30 mW, 532 nm laser and three optical parameters for detection of side scatter (SSC), orange and red fluorescence. CD4 T cell count and percentages were measured in parallel by CyFlow Counter and by a dual platform system based upon Cytomic FC 500 (Cytostat tetrachrome kit for mAbs) and Coulter HMX (for absolute cell count). All measures were performed in triplicate.

Results: The accuracy of CyFlow MiniPOC against Cytomic FC 500 showed a correlation coefficient of 0.98 and 0.97 for CD4 T cell count and percentage, respectively (linear regression analysis). The accuracy of CyFlow MiniPOC against CyFlow Counter showed a correlation coefficient of 0.99 and 0.99 for CD4 T cell count and percentage, respectively. CyFlow MiniPOC showed an excellent repeatability: CD4 absolute number and percentage were analysed on two instruments, with an intra-assay precision below +/- 10% deviation. The sensitivity was linear in the range 0-5,000 CD4 T cells/ul. There was no effect of carry-over contamination for samples at all CD4 values, regardless of their position in the sequence of analysis.

Conclusions: The cost-effective and portable instrument MiniPOC produces reliable and accurate results that are fully comparable with highly expensive dual platform systems. Indeed, data perfectly correlate with those obtained with Cytomic FC 500/Coulter HMX. Finally, using CyFlow MiniPOC permits to perform in a fast and easy way a very high number of CD4 T cells counts per day.
623LB A Recombinant HIV-1 Gag Virus Panel for the Evaluation of p24-Antibodies and HIV Diagnostic Tests
Beatrice N. Vetter, Vanessa Orlovski, Cyril Shah, Jürg Böni, Jörg Schüpbach
National Center for Retroviruses, Zurich University, Zurich, Switzerland

Background: Diagnostically, the HIV-1 p24 protein is currently only used in HIV-1/2 Ab + Ag combination screening tests (4th generation). However, there is growing interest in new test development to extend its use to diagnosing paediatric HIV infection and disease monitoring as inexpensive alternatives to PCR-based tests. Regarding the global HIV-1 diversity, such tests should detect all subtypes with similar sensitivity. Readily available, inexhaustible tools for subtype evaluation and test comparisons are a pre-requisite for efficient test development. To this end, we developed a panel of 44 recombinantly expressed virus-like-particles (VLPs), which contain the Gag-Protease region of HIV-1 subtypes A, B, C, D, F, G, H, circulating recombinant forms 01_AE, 02_AG, BF/BG, and group O. We characterised 10 mono- or polyclonal antibodies (mAb, pAb) for their subtype-binding profiles and initiated an evaluation of commercially available 4th generation screening tests.

Methodology: Patient-derived PCR-amplified Gag-PR regions were cloned into pCMVdr8.91, allowing expression of non-infectious VLPs in tissue culture. Concentrations were standardized based on the VLPs’ reverse transcriptase activity. To assess p24 antibody binding, VLPs were lysed and coated on ELISA plates. For testing diagnostic kits, dilutions of VLPs corresponding to 2, 10 and 50 IU/mL (WHO p24 standard) were prepared in HIV-negative plasma.

Results: p24 amino acid divergence of our panel within a given subtype ranged from 4.5-8.9% and was similar to that of the Los Alamos subtype reference sequences (2.9-9.1%). Overall, weighted panel diversity was 6.8%, compared to 4.9% for the subtype-matched reference sequences. Binding profiles of p24 antibodies showed that only one mAb detected 43/44 panel members (97.7%), sensitivity for the other six mAbs ranged from 19/44 - 40/44 (43.2 - 90.9%). Subtype B and CRF01_AE were detected by the 7 mAbs most effectively (mean sensitivity 85.7%), but mean sensitivity to CRF02_AG was low (37.1%). The three pAb tested (one a pooled HIV-serum) showed a sensitivity of 100% for all subtypes except D, G and CRF02_AG (83.3%, 83.3% and 86.7%, respectively).

To date, we have tested two commercial combination screening tests and noted a large difference in performance. The ARCHITECT HIV Ag/Ab Combo assay detected all but one VLP, even at low concentration, whereas the Access HIV combo assay completely missed 16/44 subtypes.

Conclusions: Our HIV-1 Gag subtype panel has a broad diversity and served as a useful tool to assess the breadth of subtype detection. Moreover, initial results indicate that there is a need to carefully assess the capability of existing diagnostic kits for detecting the p24 of diverging subtypes.

624 Evaluation of Pima CD4 Point-Of-Care Device in Western Kenya for Potential Use in Field Settings
Clement Zeh1, Seth C. Inzaule1, Frederick Otieno1, Boaz Oyaro1, Richard Ndoro1, Rose CE1, Mitesh Desai3, Robert Chen1, Lisa A. Mills1, Taraz Samandari1
1CDC, Kisumu, Kenya, 2KEMRI/CDC, Kisumu, Kenya, 3CDC, Atlanta, GA, United States

Background: Pre-treatment loss to follow-up can be a barrier to effective antiretroviral treatment (ART) programs. CD4 point-of-care (POC) testing may reduce this by improving linkage to care. However, an implementation challenge is accuracy when operated by lay health workers (HIV testing counselors and community health workers) in field settings. We validated the accuracy of Pima’s CD4 POC device (PCD4D) when performed by lay health workers (LHW) versus laboratory technicians (LT), with LT-performed FACSCalibur as the gold standard, using capillary and venous blood from HIV-1 infected patients.

Methodology: In Phase I, we compared PCD4D performed in the laboratory by LT against FACSCalibur for 280 venous specimens. In Phase II we compared PCD4D performed by LHW versus LT from 147 paired capillary and venous specimens, and compared these to LT-performed FACSCalibur (venous and capillary). Statistical analyses included agreement

Table 1: Correlation Concordance Coefficient (CCC), absolute mean bias, sensitivity and specificity of Pima CD4 POC compared to FACSCalibur for both capillary and venous blood, operated by lay healthworkers (LHW) and laboratory technicians (LT). [Statistic, (95% CI)]
(Bland-Altman tests), correlation concordance coefficient (CCC), and sensitivity plus specificity for classification as above/below FACSCalibur-defined CD4 count of 350 cells/mm² (Kenya’s current threshold for ART initiation).

Results: Phase I: PCD4D compared favorably with FACSCalibur on venous specimens; venous sensitivity and specificity at 350 cells/mm² were both 88.9% (Table 1). Phase II: Good performance was observed for venous PCD4D results from both LHW (CCC=87, bias -86 cells/μl) and LT (CCC=91, bias -66 cells/μl). Capillary PCD4D also compared favorably; LHW (CCC=93, bias -44 cells/μl) and LT (CCC=94, bias -36 cells/μl). Venous sensitivity and specificity were 100 and 98% respectively for LT, and 94 and 95% for LHW. Using capillary blood, the sensitivity and specificity were 79 and 98% (LT) and 86 and 99% (LHW).

Conclusions: POC CD4 results were comparable to FACSCalibur for both venous and capillary specimens, when operated by both lay health workers and lab technicians. POC CD4 testing has potential to enhance HIV care and treatment programs without burdening laboratory technicians in resource limited settings.

625 Comparison of Central and Local HIV-1 RNA Quantification From Two International Clinical Trials
Janaki Amin, Matthew Law, Anthony Kelleher, Rebekah Puls, David Cooper, Sean Emery
The Kirby Institute, University of New South Wales, Sydney, Australia

Background: Central measurement of plasma HIV-RNA (pVL) is common in clinical trials. Despite the increased expense and complexity, central testing is believed to reduce variability. In the setting of two international randomised clinical trials we aim to compare trial outcomes on the basis of central and local laboratory assessed pVL.

Methodology: Data were available from ENCORE1 and SECOND-LINE study participants. Central pVL data were generated at a single laboratory from batch retrospective assay of cryo-preserved samples (Abbott m2000rt lower limit of detection (LLD) 40 copies/mL) and 33 local laboratories (LLD 20-50 copies/mL) performing a variety of real time assays under differing infra-structure constraints. The trials’ endpoint, non-inferiority between arms (Δ -10 and -12% respectively) in proportion <200 copies/mL at week 48, intention to treat missing=fail were calculated from central+local (where central was missing) and local measure alone. The distribution of log10 pVL copies/mL at week 0 was summarised and described using a Bland-Altman plot (distribution of difference ±1.95 standard deviations (lower (LLA) and upper level (ULA) of agreement) and average of test results).

Results: Of the participants in follow up at week 48, 98% had local and central pVL measures (ENCORE1 603/615, 602/615; SECOND-LINE 510/519, 508/519 respectively). The point estimates (% difference [95% confidence interval]) determined by central+local measure were very similar to those by local measure alone in both studies (1.9 [-1.9, 2.1], 2.5 [-1.6, 6.6] ENCORE1; 1.8 [-4.7, 8.3], 0.3 [-6.4, 7.0] SECOND LINE respectively). Non-inferiority in both trials was established by both determinations.

At week 0 mean pVL was greater than 4.0 log10 copies/mL in both trials on both measures. Local measures were marginally lower than central measures (mean difference pVLlog10 -0.10 and -0.17 respectively) (Figure 1). The limits of agreement were narrower for ENCORE1 than SECOND-LINE (±0.66, ±1.14 log10 copies/mL respectively).

Conclusions: The comparison of primary endpoints revealed no difference in interpretation of trial outcomes based on the use of local or central pVL measures. These data indicate that in a clinical trial setting, where the outcome of interest is pVL within routine limits of detection, central laboratory testing is not warranted.

![Figure 1. HIV RNA log10 copies/ml difference (local-central) versus average of values, with limits of agreement, by trial.](image-url)
HIV-1 Can Be Confirmed by Bio-Rad Geenius™ HIV 1/2 Confirmatory Assay Using Dried Blood Spots

Carolina Fernández McPhee1, Patricia Alvarez2, Luis Prieto3, Jacinta Obiang4, Pedro Avedillo5, Antonio Vargas6, Pablo Rojo7, José Tomás Ramos8, África Holguín9

1Microbiology and Parasitology, Hospital Ramón y Cajal, Madrid, Spain, 2Hospital de Getafe, Madrid, Spain, 3Ministerio de Sanidad y Bienestar Social, Hospital Provincial de Bata, Bata, Equatorial Guinea, 4Instituto de Salud Carlos III-Madrid, RICET, Centro Nacional de Medicina Tropical, Madrid, Spain, 5Hospital Doce de Octubre, Madrid, Spain

**Background:** Confirmatory assays for HIV diagnosis are not well implemented in limited income settings, impeding an early HIV detection and, consequently, delaying the prescription of antiretroviral treatment in the infected population. Bio-Rad Geenius™ HIV 1/2 Confirmatory Assay is a single-use immunochromatographic test for the confirmation and differentiation of individual antibodies of HIV-1 and HIV-2 in venous whole blood, serum or plasma samples. Since plasma/serum is difficult to collect and/or process in remote settings from limited resource countries and in mobile populations, our objective was to validate for the first time the assay Geenius™ HIV 1/2 for diagnostic use utilizing dried blood spots (DBS) specimens.

**Methodology:** Geenius™ HIV 1/2 test was performed to confirm the HIV infection in 70 women previously diagnosed as HIV-1 positive by one to three rapid tests using whole blood samples in the Hospital of Bata, Equatorial Guinea, from November 2012 to August 2013. DBS specimens were prepared by adding two drops of blood to fill each circle of 903 filter paper cards (GE Healthcare). Cards were dried overnight at room temperature and stored at −20°C until their shipping at room temperature to Madrid, Spain for testing. After their arrival, they were stored at −80°C until use. Blood from one DBS circle per patient was eluted in 150 µl elution buffer for 1 hour with gentle rotation. The test was performed according to the manufacturer indications, but using 40 µl of the eluted circle as specimen. The results obtained from Geenius™ HIV 1/2 were confirmed by western blot (New Lat Blot I, Bio-Rad) using the same elution volume.

**Results:** Geenius™ HIV 1/2 (Bio-Rad) successfully confirmed the HIV-1 infection using DBS in all 70 tested women from Equatorial Guinea with at least one positive rapid test and only using a low volume of eluted dried blood. No HIV-1/HIV-2 coinfections were found in the study cohort. The HIV-1 positivity was confirmed in all cases in DBS by western blot (Bio-Rad).

**Conclusions:** This is the first report that proves a good performance of Geenius™ HIV 1/2 assay (Bio-Rad) for the confirmation of the HIV-1 infection using only two drops of dried blood. Our results approve the utility of this rapid confirmatory assay using a low volume of dried blood when a lack of adequate infrastructure to collect, store or transport plasma or serum is found. DBS are a practical alternative for plasma to HIV serological diagnosis.

### Performance of SD Bioline HIV/Syphilis Duo Test in Well-characterized Serum Specimens

**Background:** The WHO and UNAIDS recommend an integrated strategy for the elimination of congenital syphilis and mother-to-child transmission of HIV. Laboratory-based syphilis diagnostics are complex and implementation can be hampered by logistical difficulties. Recently, test developers have created rapid tests that can detect multiple infections with the same specimen using a single device. The SD BIOLINE HIV/Syphilis Duo qualitative test uses a solid phase immunochromatographic assay to detect antibodies to all isotypes (IgG, IgM, IgA) specific to HIV-1 including subtype-O, HIV-2 and *Treponema pallidum* characterized serum specimens for detection of HIV antibodies and *Treponema (T.) pallidum* particle agglutination assay (TPPA) or *T. pallidum* Hemagglutination Assay (TPHA) and rapid plasma reagin (RPR) for detection of *T. pallidum* and enzyme immunoassay (EIA), Western Blot, and rapid tests for the detection of HIV antibodies. We calculated the sensitivity and specificity of test performance from the pooled data using the exact binomial method.

**Results:** The test performance from each site is displayed in the table. The pooled sensitivity for the HIV antibody component was estimated to be 99.89% (95% CI: 99.39% to 100%) and the specificity was 99.86% (95% CI: 99.25% to 100%). For the *T. pallidum* component, the pooled sensitivity was estimated to be 99.80% (95% CI: 98.89% to 99.99%) and the combined specificity was estimated to be 99.71% (95% CI: 99.16% to 99.94%).

**Conclusions:** The sensitivity and specificity of the SD Bioline HIV/Syphilis Duo test using serum were very high at each site for HIV and *T. pallidum* antibodies when compared to the gold standard testing. This dual test could be a timely breakthrough for the UNAIDS and WHO strategy for the dual elimination of HIV and syphilis. The Bioline HIV/syphilis duo test should be considered for improved coverage of screening for HIV and syphilis infections.
628 High Hepatitis C Infection Rate in Birth Cohort Testing of an Urban, Primary Care Clinic Population

1MedStar Health Research Institute, Washington, DC, United States, 2MedStar Washington Hospital Center, Washington, DC, United States

Background: CDC and USPSTF recommend all persons born within 1945-1965 (Birth Cohort) be tested for hepatitis C (HCV) at least once, given a 3.25% prevalence rate, five times higher than among adults born in other years. Additionally, though the reported rate of HCV in US population are three times higher than that of HIV, Washington DC has reported rates of 2% and 2.6% respectively. We hypothesize that HCV testing in a large, urban primary care clinic, regardless of ascertainment of risk factors, will reveal higher rates than those previously published in the US.

Methodology: Beginning December 2012, we established a HCV testing program in the Primary Care Clinic at MedStar Washington Hospital Center, with CDC grant funding (HepTLC), to sequentially test in this Birth Cohort, link directly to care, and create a sustainable testing program. Eligibility includes: born between 1945-1965, without predetermined risk factors, and not previously HCV tested or positive. HCV antibody positive patients are linked to care with Infectious Disease or Gastroenterology regardless of RNA status. Comparisons are performed between those HCV-infected and not infected, using chi-square and Student’s t-test.

Results: As of September 26, 2013, 9% of the 1,087 tested were found to be HCV infected. Those infected had a mean age of 58.7 ± 4.9 years; 94% were African American, 56% were men, 55% were past IV drug users (IDU), and 73% had public insurance. Those infected were more likely to be men (OR 2.7 [CI95 1.8-4.1]) and have public insurance (OR 2.1 [CI95 1.3-3.4]) than in those un-infected. Of the 3,929 eligible patients, 45% missed their appointments, 28% were tested; 27% were not tested, this latter group is considered as missed opportunities. Overall clinic appointment adherence was 55%; although 87% of those HCV infected were linked with an HCV expert and 69% were adherent with their first appointment.

Conclusions: This HCV prevalence rate of 9% in this Washington, DC urban clinic is significantly higher than both the previously reported rate of 3.25% in the Birth Cohort, and the reported rate of 2% in the District of Columbia. Furthermore, those who tested positive did not have previously identified risk factors, although 55% reported a prior history of IDU once queried. Rates of testing (28%) were equivalent to rates of missed opportunities for testing (27%); factors associated with the latter need to be identified and addressed. Given these very high prevalent rates in those without pre-identified risk factors, and along with an improved therapeutic cure on the horizon, testing initiatives need to become standard of care and maintained as sustainable models.

629 Prevalence and Risk Factors of Hepatitis C Virus Infection in China’s National Methadone Program

Cynthia X. Shi, Aozhou Wu, Keming Rou, Enwu Liu, Yan Zhao, Xiaobin Cao, Changhe Wang, Wei Luo, Zunyou Wu

1National Center for AIDS/STD Control and Prevention, Chinese Center for Disease Control and Prevention, Beijing, China, 2Epidemiology, Harvard University, Boston, MA, United States, 3Health Science Center, Peking University, Beijing, China, 4Epidemiology, Johns Hopkins University, Baltimore, MD, United States

Background: Approximately 13 million people in China are infected with Hepatitis C virus (HCV), while China has over 3 million injection drug users (IDUs). Established in 2004, the Chinese National Methadone Maintenance Treatment (MMT) Program has expanded to become the world’s largest drug treatment network. Despite the large HCV-infected population in China, HCV prevalence in the National MMT Program has not been reported. We sought to assess the prevalence and risk factors of HCV infection among clients in the National MMT Program in China.

Methodology: We conducted a cross-sectional HCV seroprevalence study of all adults at enrollment into the National MMT Program from March 2004 to December 2012. The National MMT Program has 756 sites in 28 provinces. Clients provided information on gender, age, ethnicity, marital status, occupation, drug use, and injecting and needle sharing behaviors using a standardized form. Clients were screened for HIV and HCV. Local providers uploaded daily records into a real-time, online central data system. We used univariate and multivariate logistic regression analyses to determine risk factors for HCV infection.

Results: Among 304,658 clients, 166,343 (54.7%) were HCV-infected, 17,670 (5.8%) were HIV-infected, and 14,014 (4.6%) were HIV-HCV co-infected. HCV prevalence among newly enrolled clients declined each year: 67.6% in 2005, 62.9% in 2006, 61.6% in 2007, 59.7% in 2008, 55.0% in 2009, 50.3% in 2010, 50.1% in 2011, and 46.6% in 2012. Figure 1 presents the widespread geographical variation of HCV prevalence; five provinces reported...
HCV prevalence above 70% and 19 provinces reported HCV prevalence above 50%. The overall prevalence of IDU was 66.8%, and the distribution closely mirrored HCV infections (Figure 1). Univariate risk factors for HCV infection were female gender, age 30-45 years, Uyghur or Zhuang ethnicity, unmarried, unemployed, IDU, and drug use history >3 years. In multivariable analysis, the strongest correlates of HCV infection were IDU (AOR: 8.2) and drug use history >9 years (AOR: 2.0). Other risk factors for HCV infection were female gender (AOR: 1.4), age >30 years (AOR: 1.3), Uyghur or Zhuang ethnicity (AOR: 1.3), unmarried (AOR: 1.2), and unemployed (AOR: 1.1).

Conclusions: HCV prevalence remains high among clients receiving MMT in China, particularly among IDUs. These findings highlight the importance of HCV and HIV screening upon MMT enrollment in China, and suggest integration of services to prevent or reduce IDU practices.

The Burden of Hepatitis C Infection in Pennsylvania State Prisons and Implications for Treatment

Background: An estimated one million persons with undiagnosed hepatitis C virus infection (HCV) come into contact with the U.S. correctional system each year. Nevertheless, there is limited published data about the HCV prevalence among American prisoners, particularly among women. Moreover, few studies have investigated the prevalence of the various genotypes among HCV-infected prisoners, which is important for guiding treatment and predicting response. The development of new HCV agents makes this a particularly relevant time to further characterize the disease among a population of patients who often come from groups with an increased prevalence of HCV, including persons with mental health conditions, with illicit substance use, and those living in poverty, as well as persons who may have relatively increased access to healthcare while incarcerated.

Methodology: The Pennsylvania Department of Corrections screens all incoming persons for anti-HCV antibody. We performed a secondary data analysis of the anti-HCV test results for all adults entering the Pennsylvania state prison system from 2004-2012, in total and stratified by sex, birth cohort, and year of incarceration. For those patients with a positive result who underwent further testing, we examined HCV RNA and genotype data. We describe these results and the implications of the findings for HCV testing policy within prison systems as well as the treatment of inmates in the era of direct-acting agents.

Results: Among 101,727 prisoners with 130,495 unique tests, overall anti-HCV prevalence from 2004-2012 was 18.1% (95% CI 17.9-18.4). It was higher among women (31.3%) than men (16.8%) (relative risk 1.87, 95% CI 1.81-1.93) and highest among persons born before 1965. The total prevalence among persons born from 1945-1965 was 35.3% (95% CI 34.6,36.0). For all persons outside that birth cohort, the prevalence was 13.5% (95% CI 13.2-13.7). The prevalence decreased in men from 21.7% in 2004 to 14.6% in 2012, a trend not observed among women. Of 101,727 prisoners, 7633 (7.5%) underwent genotype testing, of these, two thirds had detectable HCV RNA. Of 101,727 prisoners, 3247 (3.2%) underwent genotype testing, with 76.6% having genotype 1, 0.9% having mixed genotypes that included type 1, 11.7% with genotype 3, and 9.3% with genotype 2.

Conclusions: Universal anti-HCV screening is feasible in a correctional setting. The burden of HCV among prisoners in Pennsylvania is high, particularly among women. The high concentration of HCV-infected people makes correctional settings a high-yield venue for expansion of routine HCV testing and treatment. The development of more effective therapies of short duration provides the opportunity to achieve viral eradication among incarcerated populations.
Impact of Rapid Hepatitis C Testing On Receipt of Hepatitis C Results in a Public STD Clinic
Oluwaseun Falade-Nwulia1,2, Shruti Mehta1, Mark Sulkowski1, Jackline Lasola1, Khalil Ghanem1, Patrick Chauki2, David Thomas1
1Division of Infectious Diseases, Johns Hopkins University, Baltimore, MD, United States, 2Baltimore City Health Department, Baltimore, MD, United States

**Background:** With rapid improvements in the efficacy and safety of hepatitis C treatments, the factors that will determine net treatment effectiveness are the rates of testing of high risk populations and linkage to care. Rapid hepatitis C tests have been demonstrated to be accurate in diagnosis of hepatitis C. Their impact on receipt of hepatitis C antibody results in public health settings such as sexually transmitted disease (STD) clinics is not known.

**Methodology:** Rapid hepatitis C antibody testing was implemented and routinely offered to all STD clinic attendees at the Baltimore City Health Department (BCHD) Druid STD clinic starting in June 2013. Prior to this, risk-based hepatitis C testing with a standard laboratory based ELISA, was offered at the BCHD STD clinics. We compared the rates of documented hepatitis C posttest counseling and linkage to care of those tested by the rapid method to those tested with the standard of care, ascertained by review of electronic medical records. Written documentation of provision of hepatitis C antibody results was available for patients who received rapid testing. For those who received the standard of care, failure to return to the STD clinic 6 months after laboratory hepatitis C antibody testing was considered lack of receipt of results.

**Results:** Prior to implementation of the rapid test, 767 individuals (65.5 male) received a standard hepatitis C ELISA, which requires 7 days for results to be available, between January 1, 2012 and December 30, 2012. From June 24, 2013 to September 30, 2013, 1,478 individuals were offered the rapid hepatitis C test with results available in 20 minutes, of whom 1163 (79%) accepted and received rapid hepatitis C testing. 59.5% of rapid tested patients were male. Patients receiving standard of care hepatitis C testing were on average older than rapid hepatitis C tested patients: median age (IQR); 34 (25-47) years and 28 (24-39) years respectively. Out of 137 individuals with positive hepatitis C antibody test results from the standard of care, 90 (67%) individuals received their hepatitis C antibody results. In contrast, 72 (100%) of 72 hepatitis C antibody positive individuals from the rapid tested patients received their hepatitis C antibody results, alcohol screening and posttest counseling on the day of rapid testing; p-value <0.001. Additionally for individuals found to be hepatitis C antibody positive on rapid testing, 69 (96%) of 72 had blood drawn for follow up hepatitis C RNA testing on the day of rapid hepatitis C testing.

**Conclusions:** Implementation of rapid hepatitis C tests has the potential to dramatically reduce loss to follow up and facilitate early linkages to hepatitis C care.

Hepatitis C Antigen Testing: A Reliable Alternative for Diagnosing Acute HCV Infection
Simon George Shaw, Fiona Cresswell, Gary Horner, Mohammed Hassan-Ibrahim, Martin Fisher
HIV Medicine, Brighton and Sussex University Hospitals NHS Trust, Brighton, United Kingdom

**Background:** In recent years there have been multiple epidemics of Hepatitis C (HCV) co-infection in HIV-infected populations. The early identification of acute HCV infection can have important implications for both treatment and partner notification to reduce onwards transmission. Acute HCV infection is diagnosed using HCV RNA testing methods which are more sensitive and specific then HCV antibody tests, particularly in immunosuppressed patients. Recently tests against the core antigen of HCV have become available. Our aim was to compare HCV core antigen and HCV RNA testing in the detection of early HCV infection.

**Methodology:** 100 HIV-infected individuals who presented with isolated alanine transaminase (ALT) values above the upper limit of normal at routine blood sampling (>41 IU) were tested for acute HCV infection using HCV core antigen testing (Abbott Archetect +/- Biorad), HCV RNA viral load (Abbott Real Time PCR (qRT-PCR)) and standard in house HCV antibody testing. A cut off value for quantitative HCV antigen testing of 5.0 IU/mL was used in the analysis. Sequential samples were collected over a twelve month period between April 2012 and October 2013. Retrospective testing of previously stored serum samples determined which infections were acute; chronic HCV infections were excluded from the analysis. All HCV positive patients were genotyped and entered into a co-infection clinic for assessment and treatment in accordance with local guidelines.

**Results:** The mean age of patients was 41 years (27-73), 6 were female, 77% were MSM, 6% were of Black ethnicity and 4% reported IVDU. None had pre-existing liver disease and no alternative cause of raised ALT had been previously identified. Genotype 1a or 1b predominated (90%). Fifteen cases of acute HCV were identified during the 18 months of this study screening isolated ALT rises alone. All 15 were identified by the HCV RNA PCR. HCV antigen testing initially identified 13 positive and 2 ‘indeterminate’ results; these became positive on retesting. On serology, five patients were HCV antibody negative and 4 showed only a weak positive signal at the time sampled.

**Conclusions:** With the increase in HCV infections amongst HIV-infected populations, a quick, easy and cost-effective method of testing for acute HCV is needed. HCV antigen testing may offer an alternative to HCV PCR as a screening tool in the clinical setting. Relying on HCV antibody tests as a screening tool is likely to miss some acute infections.

Hepatitis C Virus Incidence in the Amsterdam Cohort Study Among Men Who Have Sex With Men: 1984-2011
Joost W. Vanhommerig1,2, Ineke G. Stolte1, Femke A. E. Lambers1, Ronald B. Geuskens1,2, Thijis J. W. van de Laar4, Martien W. Borgdorff2,3, Sylvia M. Bruisten1, Janke Schinkel1, Maria Prens1,2
1Department of Infectious Diseases, Public Health Service, Amsterdam, Netherlands, 2Department of Medical Microbiology, Academic Medical Center, Amsterdam, Netherlands, 3Department of Clinical Epidemiology, Biostatistics and Bioinformatics, Academic Medical Center, Amsterdam, Netherlands, 4Department of Blood-borne Infections, Sanquin Blood Supply Foundation, Amsterdam, Netherlands

**Background:** Since 2000, an epidemic of hepatitis C virus (HCV) has emerged among HIV-infected men who have sex with men (MSM). Among HIV-infected MSM in the Amsterdam Cohort Study (ACS), an increase in HCV incidence was observed between 2000 and 2003. Data collected during bi-annual surveys at the Amsterdam STI clinic, suggest that the HCV epidemic among HIV-infected MSM in Amsterdam has levelled off in recent years. We updated our previous ACS analysis to examine recent changes.
Methodology: All MSM with ≥2 study visits in the ACS between 1984 and 2012 were included. HCV antibody tests were performed retrospectively for all participants until 2003. In order to update the HCV status for HIV-infected MSM, linkage with several clinical and laboratory databases took place. If no negative HCV test result was available after 2008, the last visit before 2012 was tested for HCV antibodies. HIV-uninfected MSM were tested at their first 6-monthly ACS visit after STI screening was introduced in 2009. On finding HCV seroconversion, samples from earlier visits were tested to identify the moment of seroconversion. Incidence rates were calculated and time trends were analyzed using Poisson regression. We allowed for smoothly varying trends via restricted cubic splines.

Results: Between October 1984 and January 2012, 2,080/2,457 MSM had ≥2 study visits, and they contributed a total follow-up of 17,310 person-years (PYs). Twenty-nine incident HCV infections were documented. All incident cases had been infected with HIV prior to HCV infection. The overall observed HCV incidence (per 1,000 PYs, 95% CI) was 4.5 (3.0-6.5) among HIV-infected MSM and 0.0 (0.0-0.3) among HIV-uninfected MSM. Among HIV-infected MSM, a significant increase in HCV incidence was observed after 2000 (2005 vs 2000: incidence rate ratio, IRR, 3.41, 95% CI 1.58-7.34). After 2005 however, a non-significant decrease in HCV incidence was observed (2010 vs 2005: IRR, 0.94, 95% CI 0.38-2.36). The observed and modeled HCV incidence rates over time are shown in the attached figure.

Conclusions: No incident HCV infections were found among HIV-uninfected MSM. Among HIV-infected MSM, HCV incidence rates increased significantly after 2000. However, HCV incidence seems to have levelled off in recent years, in line with recent findings from the Amsterdam STI clinic. The levelling off might be explained by an increase in testing for HCV, improved HCV treatment uptake, risk reduction, or a saturation-effect among MSM at highest risk for HCV infection.
ABT-493, a Potent HCV NS3/4A Protease Inhibitor With Broad Genotype Coverage

Teresa Ng1, Thomas Reich1, Tim Middletoun, Keith McDaniel, Dale Kempf, Liangjun Lu, Guoqiang Wang, Lijuan Jiang, Yat Sun Or
1ABBVIE Inc., North Chicago, IL, United States, 2Enanta Pharmaceuticals Inc., Watertown, MA, United States

Background: HCV NS3/4a protease inhibitors (PIs) are proven therapeutic agents used in treating chronic HCV infection. First generation PIs (boceprevir or telaprevir), when combined with pegylated interferon and ribavirin (P/R), improve the cure rate in patients harboring HCV genotype (GT) 1 infections. Their usage, however, is limited by the emergence of drug resistant variants during treatment, and their lower potency against several other HCV GTs. In addition, these agents must be combined with P/R, which leads to significant side effects in treated patients. We report here the preclinical virological characterization of ABT-493, a next generation PI identified as a lead compound by AbbVie and Enanta, with potent activity across HCV GTs, and activity against the major resistant variants selected by other PIs currently in clinical development.

Methodology: The antiviral potency of ABT-493 was evaluated in assays using subgenomic HCV replicons expressing wild-type or common drug-resistant variant proteases from a number of HCV GTs. In addition, the resistance profile of ABT-493 was determined by colony selection in replicons containing GT 1a, 1b, or 3a protease.

Results: ABT-493 inhibited replication of HCV stable subgenomic replicons containing NS3 genes from GT 1a, 1b, 2a, 3a, 4a, or 6a with EC50 values ranging from 0.85 to 2.8 nM. Of note, ABT-493 was potent against replicon containing GT3a protease, with an EC50 value of 1.6 nM. ABT-493 retained its activity against common GT1a and 1b variants at NS3 amino acid positions 155 and 168 that conferred resistance to other HCV PIs. Resistant colony selection studies in GT1a and 1b subgenomic replicon cells identified A156T in GT1a and A156V in GT1b as the most frequent variants, which conferred 1400- and 1800-fold reduced susceptibility to ABT-493, respectively. However, these variants had in vitro replication capacities of only 1.5% and 9.2% that of their corresponding wild-type replicons. In a replicon containing GT3a NS3 protease, ABT-493 selected very few colonies at concentrations ≥100-fold over its EC50 value. The colonies that survived the selection contained either A156G alone, or Q168R co-selected with Y56H, which conferred 1500- or 1800-fold reduced susceptibility to ABT-493, respectively.

Conclusions: Based on its preclinical profile, ABT-493 is anticipated to have broad genotype coverage and be active against most of the clinically important drug resistant variants selected by other PIs in GT1. It is, therefore, an excellent drug candidate to be included in the development of a direct-acting antiviral regimen for the treatment of chronic HCV infection.

Use of Dried Blood Spots for Measuring Intracellular Ribavirin-Triphosphate

Leah C. Jimmerson, Jia-Hua Zheng, Lane R. Bushman, Kyle P. Hammond, Peter L. Anderson, Jennifer J. Kiser
Pharmaceutical Sciences, University of Colorado, Denver, Aurora, CO, United States

Background: Ribavirin (RBV), a nucleoside analog, undergoes intracellular phosphorylation to a mono-(MP), di-(DP), and triphosphate (TP). RBV-TP accumulates in red blood cells (RBC) leading to ATP depletion, membrane oxidative damage, and ultimately hemolytic anemia. Therefore, measuring RBV-TP in RBC is of interest for pharmacokinetic/dynamic analyses. We describe the development and validation of a method to measure RBV-TP in RBC using dried blood spots (DBS) obtained from patients undergoing RBV-based treatment for chronic Hepatitis C virus (HCV) infection.

Methodology: Whole blood was obtained in EDTA Vacutainer tubes from HCV infected subjects receiving RBV treatment for 1 day-48 weeks. Blood was used for two sample types, DBS and RBC. For DBS, a 3 mm punch was sonicated in 500 μL 70:30 methanol:water and the lysate was extracted using a QMA cartridge to separate TP from MP and DP followed by de-phosphorylation and another solid phase extraction to further purify RBV. For RBC, blood was centrifuged and RBC were obtained from the pellet, counted, and lysed in 5 mL 70:30 methanol:water followed by an identical extraction to the DBS. Concentrations were measured using liquid chromatography-mass spectrometry. DBS results are reported as pmol/punch and RBC as pmol/10^6 cells. Precision was determined in n=6 replicates of 3 patient samples in 3 separate extractions. Storage stability (room temp., 4°C, -20°C, -80°C) was assessed up to 310 days.
ABT-530, an HCV NS5A Inhibitor With Potent Pangenotypic Activity and High Barrier To Resistance

Teresa Ng, Preethi Krishnan, Warren Kati, Thomas Reisch, Liangjun Lu, Tanya Dekhtyar, Akhter Molla, Christine Collins, Tami Pilot-Matias
AbbVie Inc., North Chicago, IL, United States

Background: NS5A plays a critical role in HCV replication. Results from clinical studies with first generation NS5A inhibitors have validated NS5A as a drug target for direct-acting antiviral (DAA) therapy. We report here the virological characterization of a next generation HCV NS5A inhibitor, ABT-530, which has a more favorable preclinical profile than earlier generation NS5A inhibitors, including broad genotype (GT) coverage, high genetic barrier to resistance, and activity against common viral variants that are resistant to other NS5A inhibitors.

Methodology: The antiviral potency and resistance profile of ABT-530 were evaluated in assays using subgenomic HCV replicon cell lines expressing NS5A from different HCV GTs. Resistant variants selected by ABT-530, as well as those commonly reported to confer resistance to other NS5A inhibitors currently in clinical development, were evaluated using chimeric replicons in transient transfection assays. The genetic barriers to resistance in HCV replicons were measured in colony selection assays.

Results: ABT-530 is a potent HCV inhibitor exhibiting broad genotype coverage with EC_{50} values ranging between 1.4 and 4.3 pM against HCV replicons containing NSSA from GT 1a 1b, 2a, 2b, 3a, 4a, 5a, and 6a. ABT-530 maintains nearly wild-type levels of activity against GT1 to GT6 chimeric replicons containing NSSA variants at amino acid position 28, 30, 31, 32, 58 or 93, commonly found to confer resistance to other NS5A inhibitors. Resistant colony selection studies with ABT-530 at 10-fold over its EC_{50} value using a GT1a replicon cell line yielded only a very small number of resistant colonies, and even fewer colonies survived selection at 100-fold over its EC_{50} value. No colonies in GT1b replicon cells survived selection using ABT-530 at 10-fold over its EC_{50} value. The most frequent GT1a NSSA variant selected by ABT-530 was Y93H, which conferred only 7-fold resistance. When resistant colony selection with ABT-530 at 10- or 100-fold over its EC_{50} value was performed on chimeric replicons containing NSSA from GT2 to GT6, there were either very few or no surviving resistant colonies, indicating that this compound also has very high genetic barriers to resistance in GT2 to GT6 HCV.

Conclusions: ABT-530 is a next generation HCV NS5A inhibitor with potent and broad genotype activity. It exhibits very high genetic barriers to resistance in different HCV GTs, and retains high levels of potency against common variants that confer resistance to other NS5A inhibitors currently in clinical development. ABT-530 is being developed for use in combination with other DAAs for the treatment of chronic infection with HCV of different GTs.
### 640 FIB-4 Outperforms Liver Biopsy in the Assessment of Prognosis in HIV/HCV Coinfection

**Juan Berenguer**, Francisco X. Zamora, Ana Carrero, Miguel Angel von Wichmann, José López-Aldeguer, María J. Téllez, José Sanz, Herminia Esteban, José M. Bellón, Juan González-Garcia, and GESIDA 3603 Study Group

1Hospital General Universitario Gregorio Marañón, Madrid, Spain, 2Hospital Universitario La Paz, Madrid, Spain, 3Hospital Donostia, San Sebastián, Spain, 4Hospital La Fe, Valencia, Spain, 5Hospital Clínico San Carlos, Madrid, Spain, 6Hospital Príncipe de Asturias, Alcalá de Henares, Spain, 7Fundación SEIMC/GESIDA, Madrid, Spain

**Background:** Liver biopsy (LB) is widely considered the gold standard in the assessment of the severity of liver disease. FIB-4 is a non-invasive test (based on platelet count, age, AST, and INR; Hepatology 2006; 43: 1317-25) to estimate fibrosis in HIV/HCV-coinfected patients. We compared the prognostic abilities of LB and FIB-4 in HIV/HCV+ patients.

**Methodology:** The study sample comprised patients from the GESIDA 3603 Study Cohort with a baseline assessment of fibrosis by both LB (METAVIR) and FIB-4. We assessed overall death (OD) and liver-related events (LRE), defined as decomposition or hepatocellular carcinoma, whichever occurred first. We used ROC curves to determine the ability of LB and FIB-4 to predict outcomes. In order to assess the association between outcome and significant fibrosis and advanced fibrosis (assessed by LB [F≥2 and F≥3] or FIB-4 [≥1 and ≥3.25]), we used Cox regression adjusted for age, sex, prior IDU, CDC clinical category, CD4+ cells, HCV genotype, HCV-RNA, and sustained viral response.

**Results:** We analyzed 903 patients. The median time (IQR) between LB and FIB-4 was 4.5 (2.2 - 12.0) months. Patients with F≥2, 590; F≥3, 354; FIB-4≥1, 755; FIB-4≥3.25, 158; SVR, 328. After a median follow-up of 63 months, 46 patients died and 71 had an LRE. The AUROCs for OD for LB and FIB-4 were 0.6241 and 0.7932, respectively; P<.001. The AUROCs for LRE for LB and FIB-4 were 0.6760 and 0.7498, respectively; P=.032. The table shows adjusted hazard ratios (95% CI) of OD and LRE according to significant fibrosis and advanced fibrosis assessed by LB and FIB-4.

**Conclusions:** We found that FIB-4 outperformed LB as a predictor of both OD and LRE. LB makes it possible to evaluate structure but not function, whereas FIB-4 enables us to evaluate function. Our results call into question the role of LB as a gold standard for assessing prognosis in HIV/HCV coinfection.

|わHR (95% CI) of OD and LRE according to different stages of fibrosis assessed by LB and FIB-4 |
|---|---|---|
|Overall death| | |
|Significant fibrosis| LB F (≥2 vs. <2) 1.757 (0.837 - 3.686) .136 |
|FIB-4 (≥ 1 vs. <1) 4.256 (0.954 - 18.219) .051 |
|Advanced fibrosis| LB F (≥3 vs. <3) 1.547 (0.836 - 2.860) .165 |
|FIB-4 (≥ 3.25 vs. < 3.25) 6.522 (3.517 - 12.095) <.001 |
|Liver-related events| | |
|Significant fibrosis| LB F (≥2 vs. <2) 2.291 (1.222 - 4.296) .010 |
|FIB-4 (≥ 1 vs. <1) 5.178 (1.589 - 16.875) .006 |
|Advanced fibrosis| LB F (≥3 vs. <3) 2.369 (1.438 - 3.904) .001 |
|FIB-4 (≥ 3.25 vs. < 3.25) 4.344 (2.654 - 7.109) <.001 |

### 641 Sustained Virologic Response and the Risk of Liver Decompensation in HCV and HIV/HCV Patients

**Temitope O. Olufade**, Li Wang, Scott Devine, Onur Baseri, Vincent Lo Re

1US Outcomes Research, Merck Sharpe & Dohme, North Wales, PA, United States, 2STATinMED Research, Dallas, TX, United States, 3Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States

**Background:** Few studies have evaluated the impact of achieving a sustained virologic response (SVR) on liver-related complications among HIV/hepatitis C virus (HCV)-coinfected patients. Our objective was to assess the effect of SVR on rates of hepatic decompensation in patients with HIV/HCV coinfection and HCV mono-infection.

**Methodology:** We conducted a cohort study among HIV/HCV-coinfected and HCV-mono-infected patients with HCV genotype 1 who were treated with interferon-based therapy in the U.S. Veterans Health Administration between October 2005 and December 2010. SVR was defined as an undetectable HCV RNA in all follow-up measurements 12 weeks after treatment end date. The primary outcome was incident hepatic decompensation (defined by one hospital diagnosis or two or more outpatient diagnoses of ascites, spontaneous bacterial peritonitis, or variceal hemorrhage). Incidence rates of hepatic decompensation (in events/1,000 person years) were calculated from the date of SVR for coinfected and mono-infected patients, by SVR status. Cox regression was used to determine adjusted hazard ratios (HRs) of dec complication associated with SVR for the co-infected and mono-infected groups.
Results: Among 467 HIV/HCV-coinfected (mean age, 55 years; 34% black; mean HCV RNA, 6.4 log IU/mL; 10% cirrhosis) and 11,395 HCV-monoinfected (mean age, 55 years; 13% black; mean HCV RNA, 6.3 log IU/mL; 12% cirrhosis) patients treated with interferon-based therapy, 113 (24%) and 3,527 (31%) achieved SVR, respectively. Incidence rates of hepatic decompensation were lower for patients who achieved SVR compared to those who did not among HIV/HCV-coinfected (4.24 vs. 13.25 events/1,000 person-years; adjusted HR=1.74 [95% CI, 0.21-14.48]) and HCV-monoinfected (3.38 vs. 16.56 events/1,000 person-years; adjusted HR=5.13 [95% CI, 3.34-7.86]) patients. Coinfected patients who achieved an SVR did not have significantly higher rates of decompensation than HCV-monoinfected patients with SVR (adjusted HR=1.67 [95% CI, 0.22-12.47]).

Conclusions: Achievement of SVR following interferon-based treatment decreased the risk of hepatic decompensation among both HIV/HCV-coinfected and HCV-monoinfected patients. Coinfected patients who achieved SVR did not have significantly higher rates of decompensation compared to monoinfected patients with SVR.

642LB GWAS Reveals New Genetic Associations With Liver Fibrosis Progression

Stephanie Dominguez1,2, Sigrid Le Clerc1, Damien Uveling1, Taoufik Labib1, Maria Winnock1, Ioannis Theodorou1, Laurent Abel1, Yves Levy1,2, Dominique Salmon2, Jean François Zagury2
1Clinical Immunology and infectious disease, Henri Mondor Hospital, Paris, France, 2INSERM U955, Creteil, France, 3Chaire de Bioinformatique, Conservatoire des Arts et Métiers, Paris, France, 4INSERM U 987 ISPED, Bordeaux Segalen University, Bordeaux, France, 5INSERM U 945, Pierre et Marie Curie University, Paris, France, 6Laboratory of Human Genetics of Infectious Diseases INSERM U880, University Paris Descartes Imagine Institute, Paris, France

Background: Genetic studies with common variants in HIV mono-infection have mainly revealed associations with HIV non-progression and elite control (notably in the HLA locus). In HCV infection, the main association results were found between IL28B variants and clearance of the virus either under treatment or spontaneously. We took the opportunity of the large French ANRS CO13 HEPAVII cohort of co-infected HIV/HCV patients to study these signals and search for additional markers associated with various phenotypes related to the course of the co-infection in a genome-wide association study (GWAS)

Methodology: We used the Illumina Omni2.5 BeadChip to genotype 439 Caucasian patients who had given their informed consent for genetic studies. We first performed the usual quality controls (SNP calling >98%, patient calling >95%, HWE >10-6, IBD 1%) and then measured the stratification using the Eigenstrat® software. We report here the early findings of GWAS screening for host genetic determinants of progression of liver fibrosis. The fibrosis stage at baseline was assessed by elastography (Fibroscan®) scoring fibrosis in kilopascal. For each single nucleotide polymorphism (SNP), the genetic association was estimated by linear regression using as covariates the age at baseline, gender, the HCV genotype, the duration of both HIV and HCV infection, alcohol and drug consumption, effective cumulative time on antiretroviral treatment, and the first two principal components of the stratification analysis.

Results: After quality control and stratification analysis, there were 412 patients left to search for genetic associations on 922,971 SNPs. Fibrosis stage was available at baseline in 399 patients. Three SNPs in two regions passed the Bonferroni threshold for genome-wide significance (5x10-8); the rs11790131 SNP located in the locus 3p21.3 in the gene LOC392288 (P=1.8x10-8), the rs73060937 SNPs (r²=1), located in the locus 3p22.1 in the gene LOC101928135 (P=4x10-8). The previously published genetic markers of HIV and HCV mono-infection did not reach this statistical significance.

Conclusions: We report new signals, reaching genome-wide significance, associated with liver fibrosis in HIV/HCV co-infected patients. Confirmation in other genetic studies is needed. These potential markers of fibrosis will be studied prospectively in the cohort as well as other phenotypes such as HIV and HCV treatment response and tolerance, HIV progression and occurrence of hepatocellular carcinoma.

643 Incident HCV Infections in the Swiss HIV Cohort Study: Natural History and Treatment Outcomes

Gilles Wandel1,2, Janine Rohrbach1, Karin Metzner1, Jan Fehr1, Marcel Stöckle1, Matthias Cavassini2, Juan Ambrosioni3, Olivia Keiser4, Hansjakob Furrer1, Andri Rauch1
1Bern University Hospital, Bern, Switzerland, 2University of Bern, Bern, Switzerland, 3University Hospital Zurich, Zurich, Switzerland, 4University Hospital Basel, Basel, Switzerland, 5University Hospital Lausanne, Lausanne, Switzerland, 6University Hospital Geneva, Geneva, Switzerland

Background: We recently observed dramatic changes in the hepatitis C virus (HCV) infection epidemic in the Swiss HIV Cohort Study (SHCS), including an 18-fold incidence increase in men who have sex with men (MSM). The long-term trends in outcomes of incident HCV infections are largely unknown. We studied the natural history, treatment uptake and outcomes of incident HCV infections between 1991 and 2012 in a nationwide cohort.

Methodology: We included all patients followed in Swiss tertiary care hospitals with a documented HCV-seroconversion. Detailed information on HCV diagnosis, treatment and outcomes, as well as reasons for not starting HCV treatment was retrieved from the SHCS database and chart review using standardized case report forms. Natural history, treatment uptake and outcomes were compared between risk groups and time periods before and after the first description of the surging HCV epidemic in MSM in 2006 using Fisher’s exact test.

Results: Of 121 HCV seroconversions, 2 were excluded due to insufficient information. Among the remaining 119 cases, 46 were MSM, 52 injection drug users, 17 heterosexuals and 4 from other HIV transmission risk groups. The proportion of MSM among patients with incident HCV infections increased from 20% before to 75% after 2006 (p<0.001). Fourteen patients died during follow-up, including 3 liver-related deaths. A spontaneous clearance was observed in 30% of cases. Fibroscan results were available for 45 (38%) individuals. The median liver stiffness was 5.9 kPa (OR 4.6-7.4) after a median follow-up time of 7.4 years (3.1-11.0), and only 5 patients were above the cut-off for liver cirrhosis (14 kPa). HCV treatment uptake increased from 29% before 2006 to 68% after 2006 (p=0.001). Among those treated, only 22% started treatment during acute infection before 2006, compared to 88% after 2006 (p<0.001). MSM were much more likely to receive HCV therapy compared to patients from other transmission groups (62% vs. 29%, p=0.01). The most frequent reason for not being treated was persistent alcohol or drug abuse (30%), followed by patient’s refusal (15%). A sustained virologic response
(SVR) was achieved in 69% and 25% (p=0.05) of those treated during acute and chronic infection, respectively. Finally, four patients experienced a re-infection after spontaneous clearance and three after HCV treatment.

Conclusions: In this nationwide representative cohort of HIV-infected patients with an incident HCV infection, treatment uptake was low, although the proportion of patients treated during the acute phase of infection increased after 2006. MSM were more likely to be treated during acute infection. If treated early, SVR rates were high, underscoring the need of increased efforts towards early diagnosis and treatment.

644 Is There Long-Term Evidence of Advanced Liver Fibrosis After Acute Hepatitis C in HIV Coinfection?
Christoph Boesecke1, Patrick Ingiliz2, Matthias Mandorfer3, Carollone Schwarze-Zander1, Florian Berger4, Marc-Antoine Valantin5, Jan-Christian Wasmuth6, Thomas Reiberger7, Stefan Maua7, Juergen K. Rockstroh7, and the NEAT study group
1Department of Internal Medicine I, Bonn University Hospital, Bonn, Germany, 2MIB, Berlin, Germany, 3Medical University of Vienna, Vienna, Austria, 4Center for HIV and Hepatogastroenterology, Düsseldorf, Germany, 5Hôpital La Pitié Salpêtrière, AP-HP, Paris, France

Background: After ten years, the epidemic of sexually transmitted acute hepatitis C (AHC) infection among HIV-seropositive MSM is still ongoing. The rate of early liver fibrosis progression after AHC is of particular interest as more advanced fibrosis progression has been described in small retrospective case series. Here we evaluate the long-term evolution of liver fibrosis in HIV-patients with persistent viremia after AHC.

Methodology: 41 HIV-infected patients from 3 European countries with diagnosed acute HCV infection since 2003 with at least 12 months of follow-up and persistent HCV viremia (chronic course or unsuccessful treatment) were repeatedly evaluated for liver fibrosis by means of transient elastography. Fisher’s exact, chi-square and Mann-Whitney U test were used for statistical analysis.

Results: All patients were male, median age was 43 years. Main routes of transmission were MSM (97.6%) and IVDU (2.4%). In 80% of patients clinical symptoms of an acute hepatic infection were missing. 78% of patients were infected with HCV GT 1 and 22% with GT 4. Median baseline HCV RNA was 1,989,500IU/ml and median CD4 T cell count 491 cells/ul. 95% of all patients received cART, 85% had baseline HIV RNA <200cop/ml. Median ALT was 401 U/l. Median follow-up time was 179 weeks (IQR 120-276). All patients had persistent HCV viremia, 11 (26.8%) due to a chronic course and 30 (73.2%) after unsuccessful early treatment.

Overall, as shown in table 1 there was no significant change in median liver stiffness over a maximum follow-up of 8 years. There was no significant correlation between liver stiffness and reason for HCV persistence (chronic course vs. unsuccessful treatment), follow-up time, BMI, alcohol or drug abuse, diabetes, lipodystrophy, cART duration, or exposure to d-drugs.

Conclusions: An episode of acute hepatitis C in HIV-positive MSM does not appear to lead towards early advanced liver fibrosis. This finding is particularly reassuring for clinicians and patients in whom HCV persists due to a chronic course or unsuccessful early treatment.

645 Hepatic Decompensation in HIV/HBV/HCV Patients and the Impact of HBV Therapy
Temitope O. Olufade1, Li Wang1, Scott Devine1, Onur Basar1, Vincent Lo Re1
1US Outcomes Research, Merck Sharpe & Dohme, North Wales, PA, United States, 2STATinMED Research, Dallas, TX, United States, 3Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States

Background: Few studies have compared rates of hepatic decompensation in HIV/HBV/HCV and HIV/HCV patients. It is also unclear if anti-HBV nucleos(t)ide analogue therapy is effective at reducing decompensation rates in triply infected patients. Our objectives were to: 1) compare the incidence rates of hepatic decompensation in HIV/HBV/HCV and HIV/HCV patients; and 2) determine the risk of decompensation associated with anti-HBV nucleos(t)ide analogue-untreated and treated HIV/HBV/HCV.

Methodology: We conducted a cohort study among HIV/HBV/HCV and HIV/HCV patients in the US Veterans Health Administration (VHA) between October 2005 and February 2012. All patients had HIV, detectable HCV RNA, and 12 months in the VHA. Chronic HBV was defined by 2 positive HBV surface antigen results and/or chronic HBV diagnoses recorded >6 months apart. Use of an anti-HBV nucleos(t)ide analogue was determined. The main outcome was incident hepatic decompensation (defined by one hospital diagnosis or two or more outpatient diagnoses for ascites, spontaneous bacterial peritonitis, or variceal hemorrhage). Follow-up began after 12 months in the VHA. Rates of decompensation were compared between HIV/HBV/HCV and HIV/HCV patients. Cox regression was used to evaluate adjusted hazard ratios (aHRs) of decompensation between triply and dual infected patients and to determine the risk of decompensation in anti-HBV nucleos(t)ide analogue-untreated and treated HIV/HBV/HCV.

Results: Among 149 HIV/HBV/HCV and 4,902 HIV/HCV patients, the incidence rate and risk of decompensation was higher in triply than dual infected patients (24.1 versus 10.8 events/1,000 person-years; aHR=2.40 [95% CI, 1.44-3.99]). The risk of decompensation was substantially increased for HIV/HBV/HCV patients with no anti-HBV nucleos(t)ide analogue use (aHR, 2.48; 95% CI, 1.37-4.49) but not for HIV/HBV/HCV patients receiving an anti-HBV nucleos(t)ide analogue (aHR, 1.09; 95% CI, 0.40-2.97) compared to HIV/HCV patients.

Conclusions: HIV/HBV/HCV patients had higher rates of hepatic decompensation compared to HIV/HCV patients. The risk of decompensation was increased among triply infected patients who did not receive an anti-HBV nucleos(t)ide analogue. Controlling HBV viremia with HBV therapy is important to reduce rates of hepatic decompensation in HIV/HBV/HCV triply infected persons.
Short-Term Risk of Decompensation Among HIV/HCV-Coinfected Patients With Significant Fibrosis

Juan Macías1, Manuel Márquez2, Dolores Merino2, Francisco Téllez2, Antonio Rivero3, Luis López Cortés3, María Mancebo1, Juan A. Pineda1

1Hospital Universitario de Valme, Seville, Spain, 2Hospital Universitario Virgen de la Victoria, Málaga, Spain, 3Hospital Juan Ramón Jiménez, Huelva, Spain

Background: Never directly acting antivirals against (DAAs) HCV are becoming available. Their efficacy and safety profile is better than that of telaprevir or boceprevir. Therefore, clinicians tend to defer therapy for patients at a seemingly low risk of liver decompensation (DC) in the short-term. Thus, individuals with F3-F4 by liver biopsy (LB) are given maximum treatment priority and therapy for those with F≥2 is often appointed for the approval of next generation DAA. However, the risk of DC for HIV/HCV-coinfected patients with F2 and F3 could be similar, not allowing safe delay in therapy in this setting. We aimed at evaluating the risk of DC among HIV/HCV-coinfected individuals according to fibrosis stage. We specifically compared the risk of DC for patients with F2 vs. F3.

Methodology: 540 HIV/HCV-coinfected patients with LB, naïve or without sustained viral response to HCV therapy, prospectively followed (1990-2013), were included in this cohort study. The date of LB was baseline (BL). Fibrosis was staged by the Scheuer’s score. Survival analyses were carried out.

Results: Median (IQR) age was 47 (43-50) years. 461 (85%) patients were men. Median (IQR) follow-up was 5.6 (3.3-8.4) years. At BL, median (IQR) CD4 cell count was 463 (304-639) cells/µL, and 380 (70%) individuals showed plasma HIV RNA<50 c/mL at BL. Fibrosis stage frequencies were: F0, 40 (7.4%); F1, 119 (22%); F2, 116 (22%); F3 129 (24%); F4 136 (25%). DC were observed in: F0, 0; F1, 5 (4.2%); F2, 7 (6%); F3 12 (9%); F4 29 (21%). For F2 and F3, DC during the first year of follow-up were observed. The probability of remaining free of DC by fibrosis stage was: at 1 year: F1, 98% (93%-100%); F298% (93%-100%); F3 98% (93%-100%); F4 85% (78%-91%); at 3 years: F1, 98% (93%-100%); F298% (93%-100%); F3 94% (86%-97%); F4 79% (70%-85%); at 5 years: F1, 91% (79%-97%); F2 86% (72%-93%); F3 78% (63%-88%); F4 66% (53%-77%). The probability of remaining free of DC for F2 was not significantly different from that for F3 (p=0.139). The factors independently associated with DC were fibrosis stage (per stage increase, hazard ratio [HR] 1.9; 95%CI, 1.4-2.6; p<0.0001) and BL platelet count (<100x103 vs. ≥100x103, HR 2.6; 95%CI, 1.3-4.9; p=0.006).

Conclusions: HIV/HCV-coinfected patients with F2 are at a risk of DC not significantly different from individuals with F3. Consequently, a similar degree of priority for therapy should be given to them.

Differential Immune Marker Levels Linked To Liver Fibrosis in HIV/Hepatitis C (HCV) Coinfection

Nasheed Moqueet1, Cynthia Kanagaratham2, Danuta Radzioch3, Sahar Saeed4, Marina B. Klein1, Canadian Co-infection Cohort

1Epidemiology, Biostatistics, and Occupational Health, McGill University, Montreal, QC, Canada, 2McGill University, Montreal, QC, Canada

Background: Liver fibrosis, which can lead to cirrhosis and fatal liver failure, advances faster in HIV/HCV co-infected individuals due in part to an elevated inflammatory profile that persists even with effective cART. Immune markers targeting various stages of the fibrosis process could aid in understanding the etiology and prognosis of HIV-HCV co-infection.

Methodology: A case-cohort study was nested in the prospective multicentre Canadian Co-infection Cohort (n=1119). HCV RNA-positive individuals free of HCV treatment, fibrosis, end-stage liver disease and chronic Hepatitis B at baseline (n=679) were included. A randomly selected subcohort (n=171) served as controls (APRI <1.5 when cases occurred), while cases (n=130) developed an APRI > 1.5 (significant fibrosis) over study follow-up. Pro-fibrogenic markers (IL-8, MIP-1α, MIP-1β, MCP-1, TNF-α, RANTES, sICAM-1 and sVCAM-1) were measured from first available plasma or serum in the subcohort and cases. The subcohort was only used to determine median and quartile cutoffs. We used Cox proportional hazards to model time to APRI>1.5 according to baseline cytokine levels and adjusted for sex, alcohol use, HCV duration, CD4 count, HIV RNA, cART interruption and baseline APRI.

Results: Overall 70% were male with median HCV duration of 19 years. At baseline, 81% were on cART, with median CD4 count of 410. Median (IQR) follow-up was 2.2 years (0.48, 3.45). In univariate analysis, above median levels of IL-8 and sICAM1 were associated with higher rates of liver fibrosis, while higher levels of RANTES had protective effects compared to below median levels. These associations held when examined at the quartile level, with follow-up was 2.2 years (0.48, 3.45). In univariate analysis, above median levels of IL-8 and sICAM1 were associated with higher rates of liver fibrosis, while RANTES and MCP-1 were protective.

After adjustment for clinical predictors, IL-8, MIP-1β, and sICAM1 remained linked to higher risk of fibrosis, while RANTES and MCP-1 were protective. (See table)

Conclusions: Co-infected patients who develop significant liver fibrosis have higher levels of pro-inflammatory IL-8, MIP-1β, and sICAM1 and lower levels of MCP-1 and HIV-suppressive RANTES, which is a natural ligand of the HIV co-receptor CCR5.

Outcome of 215 HCV/HIV-Coinfected Liver Transplant Recipients: A Prospective Multicenter Study

Jose M. Miro¹, Miguel Montejo², Marino Blanes³, Abradelo Manuel⁴, Santos del Campo⁵, Lluís Castells⁶, Antoni Rafecas⁷, Christian Manzardo⁸, Iñaki Perez¹, Antoni Rimola¹, and FIPSE investigators

¹Hospital Clinic-IDIBAPS, University of Barcelona, Barcelona, Spain, ²Hospital Universitario de Cruces, Bilbao, Spain, ³Infectious Diseases, Hospital la Fe, Valencia, Spain, ⁴Hospital Doctor Octubre, Madrid, Spain, ⁵Hospital Universitario Ramon y Cajal, Madrid, Spain, ⁶Hospital Universitario Vall d’Hebron, Barcelona, Spain, ⁷Hospital Bellvitge-IDIBELL, University of Barcelona, L’Hospitalet de Llobregat, Spain

Background: We compared the survival after liver transplantation (LT) between HCV/HIV-coinfected patients and HCV-monoinfected patients. We also identified prognostic factors in HCV/HIV-coinfected LT recipients.

Methodology: Consecutive 215 HCV/HIV-coinfected patients who underwent LT between 2002 and 2012 and followed until June 2013 at 22 Spanish centers were matched with 613 HCV-monoinfected patients who received LT during the same period at the same institutions. Other matched criteria were age (±10 years), gender, HBV infection, and hepatocellular carcinoma. All patients had serum HCV RNA positive at LT.

Results: A total of 90 (42%) HCV/HIV-coinfected and 184 (30%) HCV-monoinfected recipients died during a median (IQR) follow-up of 3 (1-6) years. Retransplantation was performed in 11 (5%) and 43 (7%) patients, respectively. Survival at 1, 3, and 5 years for HCV/HIV-coinfected and HCV-monoinfected patients, according to the different HCV genotypes, is shown in the table. Five-year survival for HCV genotype 1 in HIV-infected recipients was 40% (29-51) in comparison with 68% (63-73) for HIV-negative recipients (P<0.001). Survival rates for genotypes 2 and 3 were excellent and similar in both groups (P=0.172). In HCV/HIV-coinfected recipients, pre-transplant predictive factors of post-transplant survival (HR, 95% CI) were: HCV genotype 1 (1.94 [1.19-3.14]), MELD score (per unit increase; 1.14 [1.00-1.07]), site LT volume (>1 case/year; 0.58 [0.37-0.94]), HCV viral load (>400,000 units/mL; 1.62 [1.03-2.57]), and plasma HIV suppression on cART (0.47 [0.24-0.90]). Anti-HCV treatment with pegylated-interferon plus ribavirin was administered in 42% of recipients in each group, and sustained virological response (SVR) was achieved in 22% of HCV/HIV-coinfected patients and 37% of HCV-monoinfected patients (P<0.01). In patients with SVR, 5-year survival after anti-HCV therapy was 84% and 97%, respectively (P=0.139).

Conclusions: 1) LT is a valid option for HCV/HIV-coinfected patients with genotypes 2 and 3, but more challenging for patients with genotypes 1 and 4; however, survival greatly improves in patients with SVR to anti-HCV therapy. The new available direct-acting antiviral agents (DAA) will improve the post-LT rates of SVR and therefore the outcome of coinfeated recipients with genotypes 1 and 4; 2) Plasma HIV viral load should be suppressed before LT; and, 3) LT in HCV/HIV coinfected patients should be performed at selected sites.

Liver Fibrosis Progression Among Persons With Recently Acquired HCV Infection
Adeel A. Butt 1,2, Peng Yan 3, Vincent Lo Re 1, Marina B. Klein 1, Matthew B. Goetz 2, David Leaf 3, Matthew S. Freiberg 1, Kenneth E. Sherman 1
1University of Pittsburgh, VA Pittsburgh Healthcare System, Pittsburgh, PA, United States, 2Sheikh Khalifa Medical City, Abu Dhabi, United Arab Emirates, 3University of Pittsburgh, Pittsburgh, PA, United States, 4University of Pennsylvania, Philadelphia, PA, United States, 5McGill University Health Centre, Montreal, QC, Canada, 6VA Greater Los Angeles Healthcare System, Los Angeles, CA, United States, 7University of Cincinnati School of Medicine, Cincinnati, OH, United States

Background: Studies of natural history of HCV infection are often limited by lack of knowledge about time of seroconversion. Serial measurements of HCV antibody can provide a relatively accurate time for seroconversion. Degree and progression of liver fibrosis is a critical element in prognosis, response to treatment and outcomes. We sought to determine liver fibrosis progression in persons with recently acquired HCV infection.

Methodology: We analyzed data from the Electronically Retrieved Cohort of HCV Infected Veterans (ERCHIVES). Participants were Veterans with an initial negative and a subsequent positive HCV antibody test. We excluded those with a prior history of HCV treatment, HIV coinfection, baseline AST-to-platelet ratio index (APRI) >1.5, and <24 months of follow up. The date of seroconversion was defined as the mid-point between last negative and first positive HCV antibody test. Liver fibrosis was evaluated by APRI, determined prior to and at yearly intervals after seroconversion. We calculated the yearly change in APRI and 10-year cumulative incidence of APRI >1.5, indicating significant hepatic fibrosis.

Results: We identified a total of 4,162 persons who met the above criteria and had complete data to calculate APRI scores. The mean age was 53.9 ± 12 years, 62% were White, 26.3% Black, and 92.6% were male. Mean APRI score was 0.40 ± 0.28 at baseline and 0.60 at 10 years. The average increase in APRI was 0.023 units per year. A total of 271 (6.5%) persons had APRI > 1.5 after 10 years of follow up. Age, race, sex, body mass index and genotype were not associated with APRI>1.5.

Conclusions: Fibrosis progression in persons with recently acquired HCV infection is slow, particularly in the first 5 years. Over 10 years only, 6.5% developed significant fibrosis. These data can help in deciding whether to defer treatment while awaiting more potent and more tolerable newer regimens to treat HCV infection.

Predicting Risk of ESLD in HIV/HCV Patients for Individualized HCV Therapy Decisions
Vincent Lo Re 1, Janet P. Tate 2, Adeel A. Butt 3, Marina B. Klein 1, Cynthia Gibert 1, David Rimland 1, Matthew B. Goetz 1, Jay R. Kostman 1, Amy C. Justice 2, Russell Localio 1
1University of Pennsylvania, Philadelphia, PA, United States, 2VA Connecticut Healthcare System, West Haven, CT, United States, 3University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 4VA Connecticut Healthcare System, West Haven, CT, United States, 5University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 6VA Greater Los Angeles Healthcare System, Los Angeles, CA, United States

Background: The optimal time to treat hepatitis C virus (HCV) infection in HIV/HCV-coinfected patients is unclear. Improving the ability to identify patients who are more likely to progress to end-stage liver disease (ESLD) would help determine which patients should be targeted for therapy with direct-acting antiviral agents. We evaluated the ability of routinely collected clinical variables to predict the risk of ESLD in HIV/HCV patients.

Methodology: We conducted a cohort study among HIV/HCV-coinfected patients in the Veterans Aging Cohort Study Virtual Cohort between 1997 and 2010. Patients with detectable HCV RNA who were on antiretroviral therapy (ART) were included. The main outcome was incident ESLD, defined by hepatic decompensation, hepatocellular carcinoma, or liver-related death. Baseline variables evaluated as predictors of ESLD included: FIB-4 score (a non-invasive index of hepatic fibrosis calculated using age, platelet count, and alanine and aspartate aminotransferase levels), severe anemia (hemoglobin <10 g/dL), CD4 count <200 cells/mm³, HIV RNA >400 copies/mL, diabetes mellitus, hepatitis B coinfection, non-black race, and obesity. Cox regression was used to develop prognostic models that determined the risk of ESLD in HIV/HCV patients.

Figure: Cumulative risk of end-stage liver disease among antiretroviral-treated HIV/hepatitis C virus-coinfected patients, by FIB-4 score.

651 Level of Alcohol Use and Advanced Hepatic Fibrosis in HIV-Infected and Uninfected Patients

JP Tate1, JK Lim1, KJ Bryant1, CL Gibert3, D. Rimland4, MB Goetz5, MB Klein6, DA Fiellin1, AC Justice1, V. Lo Re7
1Yale University School of Medicine, New Haven, CT, United States, 2National Institute on Alcohol Abuse and Alcoholism (NIAAA), Washington, DC, United States, 3George Washington University School of Medicine, Washington, DC, United States, 4Emory School of Medicine, Atlanta, GA, United States, 5David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, United States, 6Department of Medicine, McGill University, Montreal, QC, Canada, 7University of Pennsylvania School of Medicine, Philadelphia, PA, United States

Background: The risk of liver disease associated with level of alcohol consumption is unclear for HIV-infected patients. We evaluated the association between alcohol use categories and advanced hepatic fibrosis by HIV and Hepatitis C virus (HCV) status.

Methodology: In HIV-infected and uninfected subjects reporting alcohol use at enrollment in the Veterans Aging Cohort Study, alcohol use was determined by responses to Alcohol Use Disorders Identification Test-Consumption (AUDIT-C) questionnaire and alcohol-related diagnoses. Use was classified as non-hazardous, hazardous/binge, or abuse/dependence. Adjusted odds ratios (ORs) of advanced hepatic fibrosis (defined as FIB-4 >3.25) associated with alcohol use categories were determined, stratified by HIV/HCV status.

Results: In 1,454 HIV-infected and 2,111 uninfected, presence of advanced hepatic fibrosis increased with alcohol use category (p-trend <0.001 for both groups). HIV-infected had a higher prevalence of advanced hepatic fibrosis than uninfected (non-hazardous drinking: 6.7% versus 1.4%; hazardous/binge drinking: 9.5% versus 3.0%; abuse/dependence: 19.0% versus 8.6%; p<0.01). In HIV infected, as level of alcohol increased so did the proportion with CD4 count <200 cells/mm3 (non-hazardous: 20%; hazardous/binge: 23%; abuse/dependence: 29%; test for trend, p<0.001) and HIV RNA >400 copies/mL (non-hazardous: 52%; hazardous/binge: 56%; abuse/dependence: 60%; test for trend, p<0.001). Both HIV and HCV increased the strength of association between alcohol use and advanced hepatic fibrosis with strongest associations seen in HIV/HCV-coinfected patients with non-hazardous drinking (OR, 13.7 [5.7–33.3]), hazardous/binge drinking (OR, 19.1 [9.0–45.8]), and alcohol abuse/dependence (OR, 24.5 [10.3–58.5]) compared to uninfected non-hazardous drinkers (Figure).

Conclusions: Advanced hepatic fibrosis was present at low levels of alcohol consumption, increased with alcohol use categories, and was greater in HIV-infected than uninfected individuals. For all categories of alcohol use, associations with advanced hepatic fibrosis were particularly strong in HIV/HCV-coinfected patients.

652 Liver-Related Death in HIV/HCV Coinfected Individuals: Who Should Be Targeted for HCV Treatment?

Daniel Grint1, Lars Peters2, Juergen K. Rockstroh3, Aza Rakhmanova4, Igor Karpov5, Massimo Galli6, Pere Domingo7, Ole Kirk2, Jens D. Lundgren2, Amanda Mocroft1

Background: The arrival of potent and less toxic directly acting agents (DAA) for treatment of HCV infection may see improved outcomes and less toxicity among HIV coinfected patients. The costs of treatment may necessitate prioritisation of those at greatest risk of liver-related death (LRD) for therapy. Further understanding of LRD among HIV/HCV coinfected individuals is urgently required.

Methodology: EuroSIDA patients with HCV coinfection and follow-up after 1/1/2000 were included. Causes of death were classified using CoDe methodology. Kaplan-Meier (KM) estimation was used to calculate probabilities of liver-related death (LRD) and competing risks Cox proportional hazards models were used to describe factors associated with LRD and non-LRD (excluding unknown causes).
Results: 470 deaths with known causes were recorded (126 liver-related) from 4204 coinfected patients during 23,621 PYFU to June 2012. Patients were mostly male (68%) IDUs (69%); fibrosis data was available in 80%. LRD rates peaked at age 35-45 (7.2/1000 PYFU; 95% CI 5.6-8.8) and were lower, 2.0 (0.9-3.1)/1000 PYFU and 4.9 (0.1-14.6)/1000 PYFU in those aged <35 and >65 respectively. In contrast, non-LRD increased with age from 14.1 (11.1-17.1) to 29.6 (6.3-52.9) in those aged <35 and >65 respectively. The KM 5-year probability of LRD increased from 0.03% (0.01-0.07) in those with <F2 fibrosis and CD4>200cells/mm³, to 0.10% (0.02-0.20), 6.7% (4.5-9.9) and 9.2% (5.4-15.4) in those with <F2/CD4<200cells/mm³, ≥F2/CD4≥200cells/mm³ and ≥F2/CD4<200cells/mm³, respectively (p<0.0001). In multivariable Cox models (Table 1), ≥F2 fibrosis was associated with 25-fold increased risk of LRD. Other predictors of LRD were lower current CD4 count, higher current HIV-RNA, raised ALT, HBsAg positivity and on-going HCV viral replication. Predictors of non-LRD were increasing age at baseline, lower current CD4 cell count and on-going HCV viral replication, ≥F2 fibrosis was not a predictor of non-LRD. After adjustment, ≥F2 fibrosis was associated with a 27-fold increased risk of LRD (shR: 27.2 (11.9-61.9)) in those with CD4≥200cells/mm³ and 50-fold when CD4<200cells/mm³ (shR: 50.7 (6.6-386.7), p=0.0012 test for interaction).

Conclusions: Untreated HIV is associated with a high risk of LRD in HCV coinfected patients, in particular in those with ≥F2 fibrosis, hepatitis B coinfection and raised ALT. Our findings support guidelines to improve CD4 cell counts prior to starting HCV treatment in patients at risk of LRD.

Inc., Whitehouse Station, NJ, United States

**Background:** The combination of MK-5172 (a highly potent second-generation HCV NS3/4 protease inhibitor) and MK-8742 (a highly potent HCV NS5A replication complex inhibitor) has demonstrated a high barrier to resistance. In part A of C-WORTHY, 62 of 63 treatment-naive, noncirrhotic patients with chronic HCV GT1 infection treated for 4-12 weeks with this combination ± ribavirin (RBV) achieved SVR12. In this study, on-treatment viral responses in an HIV/HCV GT1-coinfected population treated in part B of C-WORTHY are compared with those of the HCV-monoinfected patients treated in part A.

**Methodology:** Treatment-naive, noncirrhotic HIV/HCV GT1-coinfected patients on a stable antiretroviral regimen (raltegravir + tenofovir or abacavir with either 3TC or FTC) with undetectable HIV RNA were randomized to receive MK-5172 100 mg QD + MK-8742 50 mg QD ± weight-based RBV for 12 weeks. Virologic response was assessed using COBAS TaqMan v2.0 (lower limit of quantification <25 IU/mL).

**Significant Decrease of Liver Fibrosis in HIV-HCV Coinfected Patients Treated for HCV Infection**

Marc Arthur Loko1, Camille Gilbert1, Karine Lacombe2, Caroline Lascaux-Combe2, Gilles Pialoux2, Linda Wittkop1, Christine Katlama2, François Dabis1, Dominique Salmon2

1INSERM, Bordeaux, France, 2Assistance Publique Hôpitaux de Paris, Paris, France

**Background:** To evaluate prospectively the regression of liver stiffness and the kinetics of two biochemical tests of liver fibrosis (FIB-4 and APRI) in HIV/HCV co-infected patients treated for their hepatitis C.

**Methodology:** In the ANRS CO13 HEPAVIH Cohort, patients with HIV and chronic hepatitis C who (1) received anti-HCV treatment with pegylated interferon-α and ribavirin and (2) had a liver stiffness measurement by transient elastometry before and after anti-HCV treatment were included. The kinetics of liver stiffness, FIB-4 and APRI were characterized during therapy and thereafter in patients with sustained virological response (SVR) and in patients with treatment failure.

**Results:** Among the 160 patients included, 69 (43%) had a SVR while 91 were non responders (NR). After a median follow-up duration of 36 months (IQR: 23.4-46.3), a significant liver stiffness decrease was observed after treatment in patients who achieved a SVR. In this group, the median decrease of liver stiffness was 19% after 1 to 2 years (p=0.007), 31% after 2 to 3 years (p=0.002), and 25% after 3 to 4 years (p=0.009). Similar dynamics were observed with APRI and FIB-4 and the liver stiffness decrease was observed in cirrhotic as well as in non-cirrhotic patients. In the NR group, there was a transient but non sustained decrease in the first year following the end of treatment. In the multivariate analysis, only the SVR was associated with long-term improvement of liver stiffness (odds ratio: 2.79; 95% confidence interval: 1.19-6.51, p=0.017).

**Conclusions:** In HIV/HCV co-infected patients, liver stiffness is significantly reduced after treatment, and this improvement continues off treatment in patients who achieve a SVR.
**Results:** 59 coinfected patients were enrolled (male, 82%; black, 18%; subtype 1a, 78%) and compared with 63 monoinfected patients enrolled in part A (male, 45%; black, 11%; subtype 1a, 58%). At baseline, coinfected patients had a mean HCV RNA of 6.4 log₁₀ IU/mL compared with a baseline viral load of 6.2 log₁₀ IU/mL in the monoinfected patients. After 4 weeks of therapy all coinfected and monoinfected patients had an HCV RNA <25 IU/mL independent of RBV. Among coinfected patients, the mean decline was 6.2 with RBV and 6.1 without RBV. The HCV kinetics over the first 4 weeks of therapy were similar in patients with and without HIV coinfection (Figure 1A, RBV; 1B, no RBV). Mean viral decline in GT1a- and GT1b-coinfected patients was similar (6.1 and 6.1, respectively). The most common adverse events (AEs) were fatigue (8%; 4/50) and headache (8%; 4/50); no AE was increased in patients with HIV compared with monoinfected patients. No HIV breakthrough was detected during HCV treatment. No coinfected patient discontinued. Full on-treatment data will be available in March 2014.

**Conclusions:** Among HCV GT1-infected patients with and without HIV, the combination of MK-5172/MK-8742 ± RBV was associated with robust HCV suppression. All HIV/HCV coinfected patients had HCV RNA levels <25 IU/mL after 4 weeks of treatment. The safety profile was similar in HIV/HCV-coinfected and HCV-monoinfected patients.

**655 Slow HCV-RNA Decay and Early Resistance Predict the Risk of Failure To TVR/BOC Treatment**

Francesca Ceccherini-Silberstein1, Valeria Cento2, Vania Chiara Di Maio3, Daniele Di Paolo3, Sergio Babudieri4, Antonio Di Biagio5, Massimo Andreoni6, Giustino Parruti8, Giuliano Rizzardi7, Carlo Federico Perno6

Martino Hospital, Genoa, Italy, 5Infectious Diseases Unit, University-Hospital of Rome Tor Vergata, Rome, Italy, 6Infectious Diseases Unit, Pescara General Hospital, Pescara, Italy, 7Division of Infectious Diseases, Hospital Sacco of Milan, Milan, Italy

**Background:** Triple therapy with telaprevir (TVR)/boceprevir (BOC)+peg-IFN+RBV can achieve excellent results in terms of antiviral efficacy, but it can be burdened by failures with the development of resistance mutations (RAVs). Aim of this study was to evaluate, in clinical practice, the kinetics of HCV-RNA decay and the early appearance of RAVs, in order to identify as soon as possible patients at highest risk of virological failure under triple therapy.

**Methodology:** 126 patients (GT1a/1b/1g=46/79/1; previously non-responders/relapsers/naïve=75/31/20; cirrhotic=61 [48.4%], 2 HIV-1 co-infected) received pegIFN+RBV+TVR (N=89) or +BOC (N=37). The presence of RAVs was evaluated by population sequencing (PS) at baseline, at early time points (48h-2 weeks) and at failure. HCV-RNA was determined at early time points and then according to the standard treatment protocol.

**Results:** In this ad interim analysis, the median [IQR] time follow-up was 33 [17-62] weeks with BOC and 23 [9-44] weeks with TVR. Virological failure was observed in 31 (25%) patients (23 previously non-responders), in the 89% of cases associated with appearance of RAVs. Among patients who have completed treatment (N=64), RAVs at baseline/early time-points (48h-2weeks) were observed in 9 patients (14%); 7/9 (78%) subsequently failed treatment vs. 19/55 (35%) of patients without early RAVs (p=0.025). Among the 7 failures, 1 with T54S baseline failed without further RAVs, while 6 showed the development of complex mutational patterns (1=R155RT+A156AV, 2=V36M+R155K, 1=T54S+R155KR, 1=V36L+R155M, 1=A156T+T54S), probably as a result of viral evolution under therapy pressure. Other 2 patients had early RAVs only in quasispecies (T54AT; A156AT), and are currently SVR8.

Patients with baseline/early RAVs also showed a suboptimal HCV-RNA decay: only 10% achieved a rapid virologic response vs 49% of patients without RAVs (p=0.021). The median [IQR] decay of HCV-RNA after 48h of TVR administration was substantial (-3.0 [-3.4;-2.6] logIU/ml) and independent from the subsequent failure (p=0.941). On the contrary, 2 weeks HCV-RNA decay was significantly lower in failing patients than in those who reached the end of treatment (-3.7 [-4.3;-3.2] vs. -4.6 [-5.2;-4.0] logIU/ml, p=0.007). None of the 11 patients with undetectable HCV-RNA at 2 weeks subsequently failed treatment vs 2/27 patients with detectable HCV-RNA 100 IU/ml (p<0.001).

**Conclusions:** In the context of a PI-regimen, especially for patients with advanced disease and/or previous non response to peg-IFN/RBV, early detection of RAVs combined with a suboptimal HCV-RNA decay in the first 2 weeks of treatment, may identify patients with higher risk of viral failure and thus requiring a closer monitoring during therapy.

---

**656LB Global Origin of HCV NS3 Substitution Q80K That Is Associated With Lower Simeprevir Susceptibility**

Art F. Poon1, Richard H. Liang1, Jeffrey B. Joy1, Thuy Nguyen1, Rosemary M. McCloskey1, Mel Krajden2, P. Richard Harrigan1

1BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 2BC Centre for Disease Control, Vancouver, BC, Canada

**Background:** The substitution Q80K in HCV serine protease (NS3) is associated with reduced susceptibility to the protease inhibitor Simeprevir. Q80K has been observed predominantly in HCV genotype 1a with a prevalence of 16% in Europe and 50% in the US. Thus, FDA approval for Simeprevir has stipulated screening for Q80K. We conducted a phylogenetic analysis of HCV NS3 sequences to reconstruct the evolutionary origins of Q80K, which has significant implications for its transmission between hosts and future impact.

**Methodology:** We retrieved all published HCV NS3 sequences from the Genbank database and used pairwise alignment against H77 to trim sequences to the first 543 nucleotides. We screened for genotype 1a (n=5,021) based on phylogenetic reconstruction. Sequences were annotated with country and year of sample collection, or discarded if these data were not available. To remove repeated samples from the same host in the absence of consistent annotation, the sequences were re-aligned and highly similar sequences were pruned from the resulting phylogeny based on a branch length cutoff of 0.01 expected nucleotide substitutions per site. We used a modified version of Path-O-Gen to root the phylogeny relating the remaining n = 794 sequences, and a penalized likelihood method to estimate divergence times. A model of codon evolution was fit to the final tree using HyPhy to reconstruct ancestral sequences.
Results: We observed Q80K in 172 out of 794 (22%) HCV 1a NS3 sequences; in particular, in 115 out of 256 (45%) sequences obtained in the US. The phylogeny comprised two major clades relating sequences derived predominantly in the US or Europe, respectively. Consistent with previous estimates, the root of our phylogeny implied that genotype 1a emerged in the early 1910's. As expected, the ancestral 1a sequence reconstructed at the root encoded the wild-type Q at NS3 position 80. We mapped only seven ancestral Q80K substitution events in the phylogeny; one of these occurred deep in the US clade in a lineage ancestral to 292 observed sequences (165 of which inherited this Q80K). Thus, the vast majority (96%) of HCV 1a carrying Q80K have descended from a single substitution event from over 50 years ago. Reversions to wild-type occurred in 13 descendant lineages of this sub-clade. Five minor Q80K substitution events mapped to terminal branches leading directly to observed sequences, while a sixth mapped to a lineage relating only two observed sequences.

Conclusions: Our results suggest that the Q80K substitution that confers decreased Simeprevir susceptibility has a deep origin within the HCV genotype 1a clade and is readily transmitted between hosts. This evolutionary history may explain the currently observed differences in the prevalence of Q80K in European and US populations.

658 Protease Inhibitors To Treat Hepatitis C in the Swiss HIV Cohort Study: High Efficacy But Low Uptake
Sebastian Haubitz1, Verena Schaefer1, Juan Ambrosioni2, Matthias Cavassini3, Marcel Stoeckle4, Patrick Schmidt4, Laurent Decosterd5, Karin Metzner5, Jan Fehr5, Andri Rauch6
1Division of Infectious Diseases, Bern, Switzerland, 2Division of Infectious Diseases, Zürich, Switzerland, 3Division of Infectious Diseases, Geneva, Switzerland, 4Division of Infectious Diseases, Lausanne, Switzerland, 5Division of Infectious Diseases, Basel, Switzerland, 6Division of Infectious Diseases, St Gallen, Switzerland

Background: Combination therapy with pegylated interferon, ribavirin and protease inhibitors (PI) has become the standard of care for chronic hepatitis C virus (HCV) genotype 1 infection. However, there is limited information on treatment outcomes in HIV/HCV coinfected patients in clinical routine settings.

Methodology: Information on drug regimens, side effects and virological outcomes were collected prospectively in all SHCS participants starting PI treatment followed in one of 7 SHCS centers until July 2013. Treatment uptake and efficacy were compared to treatment outcomes before the availability of PI in September 2011.

Results: Upon approval of PI treatment, there were 717 patients with chronic HCV genotype 1 infection. Of those, 44 (6%) started PI treatment. Thirty-four patients were infected with HCV genotype 1a and 10 with 1b. The majority were male (82%) and IDU (59%). Median CD4 count at treatment start was 536 cells/μl and 91% had an HIV-RNA <50 cp/ml. Twenty-six (59%) started telaprevir, 11 (25%) faldaprevir and 10 (22%) boceprevir. PI treatment was interrupted in 4 (9%) patients due to side effects and 4 because of virological failure. The proportion of patients who achieved a rapid virological response (RVR) was 77% for telaprevir, 82% for faldaprevir and 71% for boceprevir. Extended virological response rates (EVR) were 85%, 100% and 86%, respectively.

Conclusions: Protease inhibitor based hepatitis C treatment in HIV-infected patients resulted in high virological response rates. Although treatment uptake after the introduction of PI was less than 10% of patients with chronic HCV genotype 1 infection started therapy. Therefore, the introduction of PI in clinical routine was beneficial at the individual level, but had only a modest effect on the disease burden at the population level.

659LB Boceprevir for Previously Treated HCV-HIV Coinfected Patients: The ANRS-HC27 BoceprevIH Trial

Background: Boceprevir (BOC) added to pegylated-interferon (P) and ribavirin (R) increases sustained virological response (SVR) rates in naive hepatitis C virus (HCV) genotype 1/HIV co-infected patients. There is no data in HCV/HIV-coinfected patients who previously failed PR treatment.

Methodology: Information on drug regimens, side effects and virological outcomes were collected prospectively in all SHCS participants starting PI treatment followed in one of 7 SHCS centers until July 2013. Treatment uptake and efficacy were compared to treatment outcomes before the availability of PI in September 2011.

Results: Upon approval of PI treatment, there were 717 patients with chronic HCV genotype 1 infection. Of those, 44 (6%) started PI treatment. Thirty-four patients were infected with HCV genotype 1a and 10 with 1b. The majority were male (82%) and IDU (59%). Median CD4 count at treatment start was 536 cells/μl and 91% had an HIV-RNA <50 cp/ml. Twenty-six (59%) started telaprevir, 11 (25%) faldaprevir and 10 (22%) boceprevir. Upon approval of PI treatment, there were 717 patients with chronic HCV genotype 1 infection. Of those, 44 (6%) started PI treatment. Thirty-four patients were infected with HCV genotype 1a and 10 with 1b. The majority were male (82%) and IDU (59%). Median CD4 count at treatment start was 536 cells/μl and 91% had an HIV-RNA <50 cp/ml. Twenty-six (59%) started telaprevir, 11 (25%) faldaprevir and 10 (22%) boceprevir. Upon approval of PI treatment, there were 717 patients with chronic HCV genotype 1 infection. Of those, 44 (6%) started PI treatment. Thirty-four patients were infected with HCV genotype 1a and 10 with 1b. The majority were male (82%) and IDU (59%). Median CD4 count at treatment start was 536 cells/μl and 91% had an HIV-RNA <50 cp/ml. Twenty-six (59%) started telaprevir, 11 (25%) faldaprevir and 10 (22%) boceprevir, and 10 (22%) had pre- treatment with intravenous silibinin. Twenty (45%) were treatment-naïve, 9 (20%) prior relaper and 15 (34%) prior partial or null-responder. Assessment of liver fibrosis by biopsy and/or fibroscan was available in 40 patients: 32 (80%) had significant fibrosis (≥ Metavir F2), and 9 (23%) had cirrhosis. Two patients stopped therapy due to side effects and 4 because of virological failure. The proportion of patients who achieved a rapid virological response (RVR) was 77% for telaprevir, 82% for faldaprevir and 71% for boceprevir. Extended virological response rates (EVR) were 85%, 100% and 86%, respectively.

Conclusions: PI treatment increased after the introduction of PI, less than 10% of patients with chronic HCV genotype 1 infection started therapy. Therefore, the introduction of PI in clinical routine was beneficial at the individual level, but had only a modest effect on the disease burden at the population level.
stopped HCV therapy. The W12-SVR was achieved in 34/64 patients (53%), varying according to ART regimen (ATVr: 41%, RAL: 70%, others: 40%), previous response (relapse: 90%, breakthrough: 0%, partial response: 61%, null response: 24%), HCV subtype (1a: 46%, 1b: 79%), but not to IL28 polymorphism (CC: 55%, CT: 45%, TT: 60%) nor fibrosis stage (F0-F2: 56%, F3: 43%, F4: 55%). HCV treatment was discontinued in 35 patients (55%) due to virological non response in 9 (14%), breakthrough in 7 (11%), patient’s decision in 8 (13%; 7 before W16), investigator’s decision in 1, infections in 3 (5%), general disorders in 4 (6%), acute pancreatitis in 1, neutropenia in 1 and thrombopenia in 1. Grade 4 AEs occurred in 20 patients including leucopenia/neutropenia (6%), infections (6%), anemia (3%) and general disorders (3%). W12-SVR was achieved in 7 patients who stopped prematurely HCV treatment for AEs or patient/investigator’s decision. P or R dose reduction was required in 3 and 9 patients, respectively, EPO in 38, blood transfusions in 8 and G-CSF in 7. No HIV breakthrough or death was observed. HCV NS3 protease could be sequenced in 13 patients exhibited virological failure on BOC+PR and relevant mutations (mostly R155K and V36M/A) were detected in 7, whereas absent at baseline.

Conclusions: W12 SVR rate to BOC+PR in treatment-experienced patients was similar to that described in HCV-1 mono-infected treatment-experienced patients with a low discontinuation rate for toxicity.

660 Boceprevir/Telaprevir-Based Therapy in HIV-Infection: Interim Analysis of a Multicenter Cohort
Karim Neukam†, Daniela Munteanu, Antonio Rivero, Annette Haberl, Manuel Márquez, Patrick Ingiliz, Ignacio de los Santos-Gil, Thomas Lutz, Juergen K. Rockstroh†, Juan A. Pineda†
1Unit of Infectious Diseases and Microbiology, Hospital Universitario de Valme, Seville, Spain, 2University of Liverpool, Liverpool, United Kingdom, 3Bonn University Hospital, Bonn, Germany, 4Matei Bals National Institute of Infectious Diseases, Bucharest, Romania, 5Hospital Universitario Reina Sofia, Cordoba, Spain, 6Frankfurt University Hospital, Frankfurt am Main, Germany, 7Hospital Virgen de la Victoria, Malaga, Spain, 8Medical Center for Infectious Diseases, Berlin, Germany, 9Hospital Universitario de la Princesa, Madrid, Spain, 10Infermiologikum, Frankfurt am Main, Germany

Background: Clinical trials on triple therapy against HCV infection including telaprevir (TVR) or boceprevir (BOC) plus pegylated interferon and ribavirin (PR) have reported considerably higher response rates than with PR alone. However, there is little information about the response to triple therapy used in clinical practice in these patients. This study was aimed to evaluate the efficacy and safety of triple therapy including TVR or BOC in HIV/HCV-coinfected patients in real-life conditions.

Methodology: HIV/HCV genotype 1-coinfected patients seen at 20 centers throughout Germany and Spain who received therapy including TVR or BOC plus PR for at least 4 weeks were included in this study. In patients with a lead-in phase, treatment week (TW)4 and TW12 response was evaluated 8 and 16 weeks after treatment initiation.

Results: 166 patients have been included in this study so far: 84.3% were male, 71.3% were IL28B rs12979860 genotype CT or TT and 48% individuals presented cirrhosis. Infection with HCV genotype 1a was observed in 69.9% and 75.8% showed a baseline HCV RNA load >600000 IU/mL. The most commonly used ARV drugs were tenofovir/emtricitabine [117 (70.5%) patients], boosted atazanavir [44 (26.5%) patients] and raltegravir [82 (49.4%) patients]). Of the 117 (75.5%) patients who had received previous HCV treatment, 36.8% had been null responders, 14.5% partial responders and 29.1% had relapsed. 134 subjects (80.7%) initiated treatment based on TVR and 32 (19.3%) on BOC. In an intention-to-treat approach, proportions of patients with undetectable HCV RNA, according to the time-point of follow-up were 72.1% (106/147) at TW4, and 87.5% (126/144) at TW12, 73.8% (104/141) at TW24 and 64.3% (74/115) at TW48. 41 (24.7%) patients discontinued HCV therapy [30 (18.1%) because they fulfilled stopping rules, 5 (3%) individuals due to adverse events, 5 (3%) were lost to follow-up and 1 (0.6%) patient died due to hepatic decompensations], Rash associated with TVR was observed in 8 cases (4.8%) and 27 (30.7%) individuals showed hemoglobin levels below 10mg/dl at some point of treatment. In an analysis restricted to 39 patients who had a 60 week or longer follow-up after starting therapy, sustained virological response 12 weeks after treatment discontinuation was observed in 27 (69.2%) patients. 3 (10%) out of 30 who had response at end of therapy and reached W12 after treatment, relapsed.

Conclusions: Response rates to triple therapy with TVR or BOC plus PR in HIV/HCV-coinfected patients under real-life conditions, and therefore, including a high proportion of poor responders, pretreated patients and of subjects with cirrhosis, are similar to that found in naïve patients in clinical trials. The safety profile of BOC and TVR-based therapy is comparable to that shown in clinical trials.

661 Favorable Adverse Event Profile of Sofosbuvir/Ribavirin Versus Standard of Care for Hepatitis C
Kerry Townsend, Shivakumar Narayanan, Amy Nelson, Adrian Majid, Luciano Kapeluszniak, Robert R. Redfield, Shyamasundaran Kottili, Rohit Talwani, Anuoluwapo Osunusi
1LIR, NIAID, NIH, Bethesda, MD, United States, 2Institute of Human Virology, Div. of Infectious Diseases, University of Maryland School of Medicine, Baltimore, MD, United States

Background: The treatment of Hepatitis C virus (HCV) infection is rapidly evolving from the current standard of care comprised of interferon (IFN)- based triple therapy to IFN free treatment with directly acting antiviral agents (DAAs). Triple therapy with Boceprevir (BOC) or Telaprevir has resulted in improved SVR rates, however adverse events (AEs), pill burden and drug interactions remain significant barriers to successful completion of treatment. The aim of this study was to evaluate the AEs experienced with the present standard of care compared to sofosbuvir + ribavirin (SOF/RBV) in HCV monoinfected, genotype-1 (GT-1) individuals.

Methodology: We retrospectively evaluated HCV monoinfected, treatment naive, GT-1 individuals treated with either BOC/IFN/RBV at the Veterans Affairs Medical Center, Baltimore (n=97) or SOF/RBV in the SPARE clinical trial at the National Institute of Allergy and Infectious Disease (n=60). AEs namely hematologic (hemoglobin, neutrophil and platelet counts); hepatic (alanine transaminase or bilirubin) and renal (eGFR) were measured and graded from 1 (mild) to 4 (severe) according to the DAIDS toxicity table (version 1.0). Comparisons were carried out using the nonparametric Wilcoxon rank sum and Chi square tests using GraphPad Prism 6.0.

Grading was measured from 1 (mild) to 4 (severe) according to the DAIDS toxicity table (version 1.0).  
Table_for_Grading_Severity_of_Adult_Pediatric_Adverse_Events.pdf
Results: The BOC/IFN/RBV cohort was older (58 vs. 55, p=0.0006) male (96% vs. 62%, p<0.0001) and had more advanced liver disease (59% vs. 23%, p<0.0001) (Table 1). The SOF/RBV group had a higher proportion of African Americans (83% vs. 65%, p=0.001). The combination of SOF/RBV was well tolerated, while BOC/IFN/RBV was associated with significantly more AEs, most commonly anaemia, anemia and platelets. In the SOF/RBV cohort, 5(8%) patients discontinued treatment early but none (0%) were for AEs while 34 (35%) patients on triple therapy discontinued treatment due to AEs.

Conclusions: SOF/ RBV treatment was associated with much fewer side effects than BOC-based triple therapy appearing to be a safer and more tolerable alternative for HCV GT-1 patients. These results show that emerging IFN/RBV free therapies may enhance patient compliance, allowing treatment of larger numbers of patients.

663LB IFN-Free 3 DAA Regimen in HCV Genotype 1-Infected Patients On Methadone or Buprenorphine

Jacob Lalezari1, J Greg Sullivan2, Peter Varunok3, Edward Golan4, Kris V. Kowdley5, Vinod Rustgi6, Humberto Aguilar7, Franco Felizarta8, Daniel Cohen9, Hui Tang10
1Quest Clinical Research, San Francisco, CA, United States, 2Parkway Medical Center, Birmingham, AL, United States, 3Premier Medical Group of the Hudson Valley, NY, United States, 4Northwest Gastroenterology Clinic, Portland, OR, United States, 5Digestive Disease Institute, Seattle, WA, United States, 6Metropolitan Research, Fairfax, VA, United States, 7Louisiana Research Center, LLC, Shreveport, LA, United States, 8Private practice, Babiesfield, CA, United States, 9AbbVie Inc., North Chicago, IL, United States

Background: ABT-450 is an HCV NS3/4A protease inhibitor (dosed with ritonavir 100mg, ABT-450/r) identified by Abbott and Enanta. ABT-267 is an NS5A inhibitor, and ABT-333 is an NS5B RNA polymerase inhibitor. This 3D regimen, dosed with ribavirin (RBV) in treatment-naive and experienced HCV-infected genotype 1 (GT1) patients, has demonstrated SVR12 rates of 96% after 12 weeks of treatment. We evaluated the safety and efficacy of 3D+RBV in patients receiving chronic opioid replacement therapy, a challenging population with a high prevalence of HCV.

Methodology: Non-cirrhotic patients with chronic HCV GT1 infection who were on stable methadone or buprenorphine +/- nalfonoxone therapy were enrolled in this open-label study. Patients were treated for 12 weeks with co-formulated ABT-450/r/267/267 (2 tabs OD), ABT-333 (1 tab BID), and weight-based RBV. The percentage of patients achieving SVR4 (HCV RNA < LLOQ 4 weeks post-treatment) was assessed in an intent-to-treat analysis.

Results: 38 patients were enrolled (19 on methadone, 19 on buprenorphine). Mean age was 48.2 years, 66% were male, 95% were treatment-naive, 84% had GT1a infection, and 68% had IL28b non-CC genotype. One subject prematurely discontinued due to a serious adverse event unrelated to study drug (cerebrovascular accident). The remaining 37 subjects all achieved SVR4. Complete SVR12 data will be presented. There were no virologic failures. The most frequent adverse events were nausea (50%), fatigue (47.4%), and headache (31.6%); 8 patients experienced hemoglobin < 10 g/dL while on treatment.

Conclusions: The 3D+RBV regimen was well tolerated in this population; patients achieved SVR4 rates comparable with previous trials.

666 Telaprevir Treatment of HIV/HCV G1 Patients With Severe Fibrosis: Efficacy Results To Week 16

Andrea Gori1, Manuela Donorana2, Oksana Chernova3, Jürgen Rockstroh4, Denes Bánhegyi5, Colm Bergin6, Gabriella Vecuchi7, Andrew Hill8, Blanca Hadacek9, Mark Nelson10
1Division of Infectious Diseases, San Gerardo Hospital, Monza, Italy, 2Servicio de Doenças Infecciosas, Hospital de Santa Maria, Lisbon, Portugal, 3State Healthcare Institution, Wycombe, United Kingdom, 4Division of Infectious Diseases, San Gerado Hospital, Monza, Italy, 5Digestive Disease Institute, Seattle, WA, United States, 6Metropolitan Research, Fairfax, VA, United States, 7Louisiana Research Center, LLC, Shreveport, LA, United States, 8Private practice, Babiesfield, CA, United States, 9AbbVie Inc., North Chicago, IL, United States

Background: HEP3005 is an ongoing, open-label, international clinical trial of telaprevir for patients with genotype 1 hepatitis C, HIV co-infection, and liver fibrosis/cirrhosis. Telaprevir is approved for use in patients with genotype 1 chronic HCV infection treated in combination with pegylated interferon and ribavirin. It is indicated for use in patients with fibrosis/cirrhosis, male patients, and patients <60 years of age who require treatment of HCV infection. In this open-label study, patients were treated for 12 weeks with co-formulated ABT-450/r/267 (2 tabs QD), ABT-333 (1 tab BID), and weight-based RBV. The percentage of patients achieving SVR4 (HCV RNA < LLOQ 4 weeks post-treatment) was assessed in an intent-to-treat analysis.

Results: One-hundred and eighteen patients were treated with telaprevir, pegylated interferon-alpha and ribavirin (PR) for 12 weeks, followed by PR for 36 weeks. Liver biopsy or non-invasive tests showing severe fibrosis (Metavir F3 or Ishak 3-4) or cirrhosis (Metavir F4 or Ishak 5-6) and platelet count ≥80,000/mm³ were required at entry. This interim (ITT) analysis included 16 week data from the first 102 patients who had the potential to reach Week 16 (12 weeks of TVR + PR and 4 weeks of follow up on PR alone).

Results: Mean age was 44 years and mean weight 75kg; 82% were male and 100% Caucasian, 67% had HCV RNA levels ≥800,000 IU/mL, 59%/41% had severe fibrosis/cirrhosis, 61% had genotype 1a, 34% were treatment naïve, 16% prior relapsers, 45% prior non-responders and 4% had prior viral breakthrough. Baseline HIV RNA was <50 copies/mL in 96% of patients; mean baseline CD4 count was 644 cells/μL. The ribavirin dose was 1000 to 1200 mg/day in 92% of patients. Overall, 99/102 patients continued antiretroviral treatment during the trial, while 3 were untreated. NRTIs were TDF/FTC for 62% and ABC/3TC for 34% of patients. In addition patients received either raltegravir (37%), efavirenz (21%) or atazanavir/ritonavir (46%). By Week 4, 65/102 patients (64%) had undetectable HIV RNA, rising to 86/102 (84%) by Week 12. Of the other 16 patients at Week 12, 3 discontinued for a virological endpoint, 2 had detectable HIV RNA levels (>25 IU/mL), 6 had HCV RNA levels >1000 IU/mL, 2 discontinued for adverse events and 3 discontinued for other reasons. The most common Grade 1-4 adverse events were thrombocytopenia (27%), anaemia (26%), rash (22%), and neutropenia (16%). The most common Grade 3-4 adverse events were thrombocytopenia (4%), anaemia (3%), rash (1%), and neutropenia (5%). Five patients discontinued telaprevir for adverse events (2 for anaemia, 2 for rash, 1 for asthenia). The mean reduction in CD4 count to Week 12 was 267 cells/mm³. At Week 12, 78 out of 81 patients (96%) had HIV RNA <50 copies/mL (On treatment analysis).

Conclusions: In this telaprevir early access program for HIV-HCV co-infected patients with severe fibrosis or compensated cirrhosis, 84% of patients had undetectable HCV RNA by week 12 (ITT). HIV RNA remained suppressed in patients continuing on HCV treatment. The most common adverse events were haematological; discontinuation for adverse events was uncommon (5%).
664LB Telaprevir Increases Ribavirin Toxicity Through eGFR Decrease in HIV-HCV Coinfected Patients

Laurent Cotton1, Aurelie Barral-Tran1, Corine Vincent2, Marc-Antoine Valantin3, Isabelle Fournier4, Karine Lacombe5, Stéphane Chevaliez6,7, Jean-Pierre Aboulker8, Anne-Marie Taburet4, Jean-Michel Molina1,9

1Infectious Diseases, Hospices Civils de Lyon, Lyon, France, 2U1052, INSERM, Lyon, France, 3Clinical Pharmacy, Kremlin Bicêtre, Assistance Publique - Hôpitaux de Paris (AP-HP), Paris, France, 4Ea4123, Faculty of Pharmacy, Paris-Sud University, Chatenay Malabry, France, 5SC10-US019, INSERM, Villejuif, France, 6Pitié-Salpêtrière Hospital, Assistance Publique Hôpitaux de Paris (AP-HP), Paris, France, 7UMR-S 943, INSERM, Paris, France, 8Saint-Antoine Hospital, Assistance Publique Hôpitaux de Paris (AP-HP), Paris, France, 9University of Paris VII Denis Diderot, Paris, France

Background: A significant hematological toxicity (HT) was observed during the retreatment of HIV-HCV genotype 1 coinfected patients in the ANRS HC26 TelaprevIRH study. Alterations in renal function have been described with telaprevir (TVR). We examined the relationship between ribavirin (RBV) trough concentration (C), estimated glomerular filtration rate (eGFR) and hemoglobin (Hb) level, before and after introduction of TVR in the TelaprevIRH study.

Methodology: 69 HIV-HCV genotype 1 coinfected patients received PegIFN α2a (180μg/week) + RBV (1000-1200mg/day) for 4 weeks, followed by TVR (750/1125mg tid without/with efavirenz) + PegiFN-RBV for 12 weeks and finally PegiFN-RBV for 32 to 56 weeks. RBV C was determined by HPLC at W4 and W8, before and after TVR introduction. eGFR was estimated by the MDRD equation. Hb level and eGFR were determined at baseline (BL) and monthly.

Factors associated with HT (defined by RBV dose reduction, prescription of EPO or blood transfusion) were analyzed by uni- and multivariate analysis. All data are presented as median [IQR].

Results: 67/69 patients were analyzed (female 21%, severe fibrosis/cirrhosis 40%, inosine triphosphatase (ITPA) CC 81%). Hb level was 154 g/L [145-160] at BL and declined to 131 g/L [119-143] at W4 and 116 g/L [104-129] at W8 (p<0.0001). eGFR remained normal between BL (97.9 ml/min [81.4-110]) and W4 (103.4 ml/min [87.4-122.1]), then declined to 86.3 ml/min [74.8-104.5] at W8 (p<0.0001). eGFR stabilized until W16 and increased back to BL level at W20 (98.4 ml/min [84.1-112.2]). The proportion of patients with stage 1/2 chronic kidney disease increased from 36% / 0% at BL to 50% / 6% at W8 (p=0.001) and 40% / 15% at W16 (p=0.001), then decreased to 35% / 0% at W20.

RBV C increased from 1.88 mg/L (1.48-2.29) at W4 to 2.88 mg/L (2.16-3.71) at W8 (p<0.0001). RBV C was ≥3 mg/L in 12% of patients at W4 and in 45% at W8 (p<0.0001). Female gender was marginally associated with RBV C ≥3 mg/L at W4 (p=0.05). Female gender (p=0.02) and W8 eGFR (p=0.0001) were significantly associated with RBV C ≥3 mg/L at W8.

HT was observed in 23.9% of patients at W4, 45.3% at W8 and 70% at W48. Female gender, BL Hb, BL eGFR, W8 eGFR and RBV C ≥3 mg/L at W8 were associated with W8 HT in the univariate analysis while body weight, CDC stage, CD4 cells count, type of antiretrovirals, liver fibrosis, HCV sub-genotype, ITPA genotype and SVR24 were not. In multivariate analysis, RBV C ≥3 mg/L at W8 (OR 7.7 [2.2-27.4]) and BL Hb <150 g/L (OR 6.4 [1.7-23.8]) were independently associated with W8 HT while gender, type of antiretrovirals, BL eGFR and W8 eGFR were not.

Conclusions: Association of TVR to PegiFN+RBV was associated with a decrease in eGFR and a significant increase in RBV C, leading to RBV over-exposure in 45% of the patients.

665LB Safety and Efficacy of IFN-Free, Sofosbuvir/RBV Therapy in HIV/HCV Liver Transplanted Patients

Ana Moreno1, Maria J. Pérez-Elias2, Rafael Bárcea1, Carmen Quereda1, Jose L. Casado1, Fernando Dronda1, Santos del Campo1, Maria L. Mateos1, Alberto Díaz1, Santiago Moreno1

1Infectious Diseases, Hospital Ramón y Cajal, Madrid, Spain, 2Liver Transplant Unit, Hospital Ramón y Cajal, Madrid, Spain, 3Microbiology, Hospital Ramón y Cajal, Madrid, Spain

Background: Long-term outcome in HCV/HIV-coinfected subjects undergoing liver transplantation (LT) relies on the management of HCV recurrence. Currently available peg-iFN-based therapies are associated to high toxicity and low antiviral efficacy, leading to worse outcomes in comparison to HCV monoinfected subjects.

Methodology: To describe for the first time the on-treatment safety and efficacy of the combination of 400mg/day of sofosbuvir (SFB) -a new direct antiviral agent against HCV targeting the HCV-NS5B polymerase- plus ribavirin (RBV) in 7 HIV/HCV-coinfected patients with HCV recurrence after LT.

Results: Mean age 49±7, male 57%, 71% prior AIDS, 100% undetectable HIV-RNA, median CD4 counts 160 cells/ml (47-451), 71% HCV-G1 (n=5), HCV-G3 (n=1), HCV-G4 (n=1). Most subjects (71%) were IL28B non-CC. Only P2 was completely naive to anti-HCV therapy (14%). Previously to SFB/RBV 57% (n=4) had already received post-LT antiviral therapy, with standard peg-iFN/RBV (n=2, null response in both), or triple therapy with boceprevir (n=1) or telaprevir (n=1), in both with premature discontinuation due to life threatening toxicity despite negative HCV-RNA. All subjects showed histological severity: cirrhosis 71% (n=5, 60% CHILD-PUGH ≥B and prior decompensation in 40%), 29% (n=2) fibrosing cholestatic hepatitis (FCH), both female with HCV-G1. Overall 86% were on tacrolimus-based immunosuppressive therapy, 43% were currently on steroids. All patients were on raltegravir-based HAART: 4 with KIVEXA™ (fixed dose 3TC/Abacavir), 3 with TRUVADA™ (fixed dose FTC/Tenofovir), P7 also received maraviroc. Median time from LT to therapy was 900 days (88-1932). To date, the median time on SFB/RBV is 7 weeks (2-40) and three (43%) have completed at least 12 weeks. Median baseline HCV-RNA was 5.73log10 IU/ml. Median HCV-RNA decreases during therapy: w+2, -3.94log10 IU/ml w+4, -4.15log10 IU/ml; 100% of patients with at least 4 weeks of therapy (n=6) reached RVR (<15 IU/ml at w+4). During therapy there were no cases of HCV-RNA or HIV-RNA rebound. Median initial dose of RBV was 800mg/d, with dose adjustments needed in 4 subjects (57%), all of them within the first 8 weeks, in three with blood transfusions. EPO was transiently used only in P3 (FCH). Liver transaminases reached normal vales within the fist two weeks in 100%. There were not premature discontinuations, infections, or SFB-related adverse events.

Conclusions: An IFN-free, SFB/RBV regimen showed an excellent safety and efficacy profile in HIV/HCV-coinfected patients with severe liver damage related to HCV recurrence after LT. 100% reached RVR, with rapid normalization of liver function tests. Viral response was the rule regardless baseline HCV-RNA, IL28B or HCV genotype, or previous pattern of response to peg-iFN based therapy.
**666 ss469415590 Variant Is a Better Predictor Than IL28B rs12979860 of PegIFN-α/RBV Therapy Failure**

Sandra Franco1, Ester Aparicio1, Mariona Parera1, Bonaventura Clotet1,2, Cristina Tural1,2, Miguel Angel Martinez1
1IrsiCaixa, Hospital Universitari Germans Trias i Pujol, Universitat Autònoma de Barcelona, Badalona, Spain, 2Fundació de la Lluita contra la SIDA, Badalona, Spain

**Background:** Recently, it has been discovered, upstream of the interferon-λ3 protein (IFNL3) (also termed IL28B) on chromosome 19, a new transiently induced region that harbors a dinucleotide variant ss469415590 (TT or ΔG), which is in high linkage disequilibrium with rs12979860. ss469415590 (ΔG) is a frameshift variant that creates a novel gene, designated IFNL4, which is moderately similar to IFNL3. Importantly, ss469415590 may have a functional role in the innate immune response to HCV. Since there are no data about the impact of IFNL4 ss469415590 polymorphisms on treatment outcomes in HCV/HIV-1 coinfected patients, we decide to investigate the role of the ss469415590 SNP in a well characterized cohort of HCV/HIV-1 coinfected patients that were treated with pegIFN-α/RBV.

**Methodology:** The prevalence of the ss469415590 TT/ΔG substitution, as well as the rs12979860 polymorphism, was analyzed in a cohort of 207 patients from our clinic with chronic HCV and HIV-1 coinfection and with a known response to treatment with pegIFN-α/RBV at 24 weeks post-treatment. ss469415590 and rs12979860 genotyping was performed using the ABI TaqMan allelic discrimination kit and the ABI7500HT Sequence Detection System. The association of ss469415590 and rs12979860 polymorphisms with response to treatment was performed by univariate and multivariate logistic regression as implemented in the SNPStats software.

**Results:** ss469415590 and rs12979860 polymorphisms were in strong linkage disequilibrium (R2 = 0.95) and both had a minor allele frequency of 0.32. The ss469415590 minor allele frequency was identical to that found for Europeans in the HapMap samples (0.07 frequency in Asians, 0.32 frequency in Europeans and 0.73 frequency in Africans). We next correlated the ss469415590 and rs12979860 genotypes with the HCV pegIFN-α/RBV treatment response. Both polymorphisms were associated with response to treatment. However, ss469415590 had a more significant association with response to treatment (OR = 3.12, 95% CI 1.17-5.67, P = 0.0001) than rs12979860 (OR = 2.60, 95% CI 1.45-4.69, P = 0.0012). Remarkably, ss469415590 had also a stronger association in a multivariate model, after adjustment for age, sex, HCV RNA load and fibrosis stage (OR = 3.56, 95% CI 1.80-7.03, P = 0.0002) than rs12979860 (OR = 2.99, 95% CI 1.53-5.84, P = 0.001).

**Conclusions:** These results demonstrate that ss469415590 is a better marker of sustained viral response than rs12979860.

---

**667 Pill Burden & Treatment Length Reduce Adherence to IFN-Free Hepatitis C Therapy in an Urban Cohort**

Tess Petersen1, Lori A. Gordon1, Kerry Townsend1, Monica Calderon1, Sreetha Sidharthan1, Rachel Silk1, Anu Osinusi1, Shyam Kottill1, Anita Kohli1,4
1Critical Care Medicine Department, National Institutes of Health Clinical Center, Bethesda, MD, United States, 2Clinical Center Pharmacy Department, National Institutes of Health, Bethesda, MD, United States, 3National Institute of Allergy and Infectious Diseases, Laboratory of Immunoregulation, National Institutes of Health, Bethesda, MD, United States, 4Clinical Research Directorate/Clinical Monitoring Research Program, Leidos Biomedical Research, Inc (formerly SAIC–Frederick, Inc), Frederick National Laboratory for Cancer Research, Frederick, MD, United States, 5Department of Infectious Diseases, University of Maryland, Baltimore, MD, United States

**Background:** Potent oral directly acting antiviral (DAA) HCV therapy with low pill burdens and short therapeutic courses are promising replacements for interferon and ribavirin based regimens. The impact of these improvements on patient adherence and virologic outcomes has not been described.

**Methodology:** Sixty HCV infected, treatment naive, genotype 1 patients were enrolled into 3 arms of a phase 2 clinical trial and received: sofosbuvir + ledipasvir (400/90mg one pill once daily in a fixed dose combination (FDC) for 12 weeks, FDC + GS-9451 (80mg/day), two pills, once daily for 6 weeks, or FDC + GS-9669 (500mg/day), three pills, once daily for 6 weeks. Serial measurements of virologic correlates (HCV RNA; deep sequencing of viral mutations) were performed. Adherence was measured using three tools: MEMS caps (MEMS), pill counts (PC) and patient report (PR). Demographics and modified ACTG questionnaires were used to determine risk factors for non-adherence. Adherence tools, treatment arms, and risk factors were compared using Pearson correlations, T-tests/ANOVA and Chi-squared tests respectively.

**Results:** In three arms, mean adherence was 92% (95% CI 88-96) using MEMS, 94% (95% CI 92-96) using PC, and 95% (95% CI 93-97) using PR. There were no statistically significant differences in adherence by treatment arm (p > 0.05). Adherence declined with increasing pill burden (p = 0.02). Adherence declines during 12-week treatment duration (*p=0.04, Week 0-4 vs. Week 8-12)

**Figure 1:** A: Adherence declines with increasing pill burden (p=0.02). B: Adherence declines during 12-week treatment duration (*p=0.04, Week 0-4 vs. Week 8-12)
Results: Patients enrolled were African American (88%), male (72%) with ≤ 12th grade education (61%). Psychiatric disease (43%) and recent history of drug/ETOH abuse (37.5%) were common.

Adherence to DAA regimens declined with increasing pill burden (99.3 ± 1.6% vs. 97.2 ± 3.6% vs. 94.8 ± 7.4%, one, two & three pills/day respectively, p=0.02 (Fig 1A)). Adherence to therapy declined significantly during the 12-week treatment course (98.1 ± 0.9% vs. 95.0 ± 1.2% weeks 0-4 vs. weeks 8-12, p=0.04 (Fig1B).) Missed doses by MEMS correlated with PC (R2=0.24, p<0.0002), but neither with PR (p=0.14 & p=0.84 respectively). Three patients missed ≥2 consecutive doses. Adherence was similar in patients with and without early viral suppression (<LLOQ at week 4) and time to viral suppression similar between adherent and non-adherent (defined as 0.05). Risk factors for non-adherence were being inconvenient (p=0.03) and children living at home (p=0.01). Common reasons for non-adherence were feeling that drugs were working (39%), forgetting (35%) and absence from home (32%).

Conclusions: Adherence to short courses of DAA therapy with 1-3 pills once a day was excellent in an urban population with multiple risk factors for non-adherence. Increased pill burden and duration of treatment decreased adherence. Continued education regarding adherence despite on-therapy viral load decline may improve outcomes.
HCV-infected individuals: (2) diagnosed and aware of their infection; (3) with access to outpatient care; (4) HCV RNA confirmed; (5) disease staged by liver biopsy; (6) prescribed HCV treatment; and who (7) achieved sustained viral response (SVR). Studies were excluded if they were not relevant to study questions, focused on specific populations, did not present original data, involved only a single site, were conducted outside of the US, or only included data collected prior to 2000. Bibliographies of included studies were reviewed for additional studies, and experts were contacted to ensure no relevant studies were missed. For each key question for which multiple studies were identified, we used meta-analytic techniques to quantitatively summarize the estimates.

**Results:** Of the 9,581 articles identified, 120 were retrieved for full text review and 7 met inclusion criteria (1 study for questions 1-5, 2 for question 6, and 3 for question 7). Overall, 3.5 million people have chronic HCV infection in the US. Fifty percent (95% Confidence Interval 43-57%) are diagnosed and aware of their infection; 46% (41-51%) are able to access outpatient care. Twenty-nine percent (28-30%) receive confirmatory HCV RNA testing, 20% (19-21%) undergo fibrosis staging, 17% (16-17%) are prescribed antiviral therapy, and 9% (9-10%) achieve SVR. (Figure)

**Conclusions:** The proposed HCV treatment cascade provides a framework for identifying gaps in HCV care, indicating that continued efforts are needed to improve diagnosis and awareness of infection, liver fibrosis staging, prescription of antiviral therapy, and achievement of SVR.

**670 Initial Results of a Community-Based Rapid Hepatitis C Testing and Linkage To Care Program**

Christian B. Ramers¹, Robert Lewis¹, Letty Reyes¹, Alexander Kuo¹, David L. Wyles¹

¹Special Populations, Family Health Centers of San Diego, San Diego, CA, United States, ²Hepatology and Liver Transplantation, University of California San Diego Health Sciences, San Diego, CA, United States, ³Infectious Diseases, University of California San Diego Health Sciences, San Diego, CA, United States

**Background:** Chronic Hepatitis C virus (HCV) is a major public health concern and the leading chronic viral cause of death in the United States. Some estimates suggest that less than 50% of those infected with HCV are aware of their infection. Community-based testing strategies are needed, but uncertainty exists surrounding the implementation of HCV testing, linkage to care, and treatment.

**Methodology:** We conducted a rapid testing and linkage to care program at urban community health centers and alcohol and drug treatment programs. HIV test counselors were cross-trained on HCV testing and counseling. Demographic and risk-factor data was collected prospectively. Rapid HCV Antibody testing was followed immediately by post-test counseling, phlebotomy for confirmatory viral load testing, and linkage to care.
Results: Between 4/23/13 and 9/5/13 we conducted 453 rapid tests at 3 clinic sites and 6 residential alcohol and drug treatment programs. 94 rapid tests (21%) were positive. Of those patients with positive rapid HCV Ab tests, 12 (12.7%) refused confirmatory testing. 82 patients had confirmatory viral loads drawn with 59 (71.9%) positive and 23 (28%) undetectable indicating resolved infection. Of the 94 HCV Ab positive patients, 63 (67%) were male and 38 (40.4%) fell within the ‘baby boom’ birth cohort of birth year between 1945-1965. 47 (50%) disclosed a prior history of injection drug use. The median age was 44 (range 22-64). Only 25 of 94 (26.5%) had insurance, and of these, all but 2 were publicly funded (Medicaid or Low Income health insurance). Overall, 67 (71.2%) were linked to care and one started treatment.

Conclusions: This demonstration project reports a very high seroprevalence of HCV in urban community health centers and alcohol and drug rehabilitation centers. Many patients refused confirmatory blood draws, and only half reported prior injection drug use. Only one quarter of all HCV Ab positive patients had insurance at the time of testing, and of those who were insured, their plans would generally not cover HCV treatment. Stigma, denial, lack of healthcare insurance, and lack of coverage for HCV treatment are significant obstacles to the effort to address the HCV epidemic.

671 The CORE HCV Cascade a Decade Later: Looking Ahead To an IFN-Free Era
Oluwatoyin M. Adeyemi, Stephan Effinger, Benjamin Go, Sonia Vibhakar, Maureen Gallagher, Deborah Wolen, Becky Goldberg, Mike Demetria, David Barker, Gregory Huhn
Ruth M Rotstein CORE Center, Cook County Health and Hospitals System, Chicago, IL, United States

Background: One of the goals of the US National Viral Hepatitis Plan is to increase testing, linkage to care and treatment of HCV. Our HIV center has had an on-site multidisciplinary hepatitis clinic since 2001 and patients (pts) have access to all approved HCV medications regardless of ability to pay. In this study, we determined HCV evaluation and treatment rates in HIV/HCV co-infected pts through 2013.

Methodology: Retrospective electronic chart review of all HIV+/HCV ab+ pts with >1 clinic visit at the CORE center Chicago from Jan 2006- July 2013. HIV+/HCV+ pts were classified into 2 cohorts: Lost to Care (LTC) cohort; Last primary care clinic visit between Jan 2006-Dec 2010 and Active cohort (AC); most recent clinic visit between Jan 2011- July 2013.

Results: Since Jan 1 2006, 1905 HIV+/HCV+ pts have had ≥1 HIV primary care clinic(PCC) visit at CORE. There were 735 pts in the LTC cohort and 1170 in the active cohort. The LTC cohort had a median age of 54 yrs, 72% were male, 70 % AA, 18% white and 12% Hisp. Median CD4 at last visit was 337 and 55% had undetectable HIVRNA. Only 16% of the LTC cohort had ≥1 hepatitis(hep) clinic visit while in care and this ranged from 9% of pts with last PCC visit in 2006 to 28% of those with last PCC visit in 2009. The AC (n=1170) have a median age of 52 years and 73% are male, 69% AA, 18% Hisp and 12% white. 762 (65%) have had ≥1 hep clinic visit through July 2013; for 238 (20%) last PCC visit was in 2012 and for 170 (15%)last PCC visit was in 2011. Median CD4 of the AC is 428 cells/mm3 and 71% have undetectable HIVRNA. 37% of the AC have had ≥1 hep clinic visit (median=7).The HCV cascade for the AC is shown in the table. *Of 631 pts with HCV genotype done; 514 (81%) were genotype1. 87% of the active cohort is <federal poverty level (FPL). 60% are uninsured, 29% on Medicaid, 5.5% on Medicare and <2% have private insurance.

Conclusions: The vast majority of HIV/HCV co-infected Pts in our clinic have not been evaluated in the hepatitis clinic and only a minority have been treated for HCV. Limitations of the current HCV therapies (tolerability and patient/provider issues) remain major barriers to HCV treatment in our co-infected pts. we expect that the numbers evaluated and treated will increase with improved treatment options in the near future. Many co-infected pts are< FPL thus, ready coverage of approved HCV medications by publicly and privately funded health plans need to be advocated for.
The Hepatitis C Cascade of Care Among HIV-Infected Patients Following Diagnosis of HCV Infection
Edward R. Cachay¹, Lucas Hili², David Wyles³, Francesca Torriani⁴, Bradford Colwell⁵, Craig Ballard⁵, William Christopher Mathews⁶
¹Medicine, University of California San Diego, La Jolla, CA, United States, ²Pharmacy, University of California San Diego, La Jolla, CA, United States

Background: Guidelines recommend screening for hepatitis (HCV) in all HIV-infected individuals, but little is known about factors influencing HCV treatment referral and disposition following HCV diagnosis. We therefore conducted this study to investigate the HCV cascade of care for HIV patients with known HCV diagnosis and to identify reasons for not starting HCV therapy after completion of HCV treatment staging.

Methodology: Retrospective cohort analysis of HIV-infected patients under care at UCSD Owen Clinic between 2008-2012. HCV-infected patients (HCV+ antibody and/or detectable HCV viral load) were categorized based on HCV treatment referral status. Bivariate analyses were conducted to investigate factors associated with lack of referral for HCV therapy. Definitions of barriers to care included: ongoing alcohol and/or drug use, uncompensated neuropsychiatry disease, uncontrolled AIDS and/or lost to follow-up attributed to alcohol or drug use.

Results: The cohort included 751 HIV/HCV+ infected patients: 84% male, 33% non-white, 20% Hispanics, 63% HIV viral load < 40 copies/ml. Median age (range) in years was 48 (19-75) and CD4+ count/mm³ was 397 (5-1777). The main routes of HIV acquisition included 30% MSM, 20% MSM + IDU, 14% heterosexual + IDU, 10% heterosexual not IDU and 3% hemophiliacs. Of the 301 (40%) patients who were referred for HCV treatment, 281 attended at least 1 HCV clinic visit. In comparison to the HCV referred group, patients who were not referred for HCV therapy had a higher proportion of non-white patients (36 vs. 28%, p=0.019) and detectable (>40 copies/ml) HIV viral load (39 vs. 32%, p=0.047). There were no differences between HCV groups in gender distribution, median age or CD4+ count. A total of 88 patients initiated HCV therapy. Of those, 22 were treated with HCV triple therapy (pegylated interferon, ribavirin and telaprevir), and 41 patients were cured of HCV (figure 1). The main reasons for not starting HCV treatment after evaluation (n=193) were: ongoing barriers to care [78(40%)]; patient choice to wait for interferon-sparing regimens [43(22%)]; decompensated cirrhosis [33(17%)]; prior HCV treatment failure with low chances of eradication with available HCV therapies [16(8%)].

Conclusions: Most HIV-infected patients with known HCV infection are not referred for HCV therapy, with minorities being referred least. The most frequent reason for not initiating HCV therapy among those assessed is the presence of ongoing barriers to care.

Assessing HCV Acquisition Routes in HIV-Infected MSM Using Single Genome Sequencing-A Pilot Study
Daniel S. Fierer¹, Andrew H. Talal¹, Kristen M. Marks¹, Wouter O. van Seggelen¹, Andrea D. Branch¹, Shirish Huprikar¹, Shuyi Wang⁵, George M. Shaw⁵, Hui Li⁵
¹Infectious Diseases, Mount Sinai School of Medicine, New York, NY, United States, ²Gastroenterology, University of Buffalo School of Medicine, Buffalo, Buffalo, NY, United States, ³Infectious Diseases, Weill Cornell Medical College, New York, NY, United States, ⁴Liver Diseases, Mount Sinai School of Medicine, New York, NY, United States, ⁵Microbiology, University of Pennsylvania, Philadelphia, PA, United States

Background: The international epidemic of hepatitis C virus (HCV) infection is in its second decade among HIV-infected men who have sex with men (MSM) but little is known about mechanisms of transmission. Our prior case control study in New York City found unprotected receptive anal intercourse as the main risk factor for acquisition, but studies in England and Germany suggest that group sex or anal trauma are the main risk factors. We sought to understand whether significant disruption of the anorectum is required for HCV acquisition among HIV-infected MSM.

Methodology: We used single genome sequencing (SGS) to identify and enumerate transmitted HCV genomes to test the hypothesis that sexual transmission would be associated with few transmitted genomes, parenteral infection through injection would be associated with many, and bloody or
traumatic sex would be associated with an intermediate number of transmitted genomes. Detailed sex and drug histories and plasma were obtained during acute HCV infection in HIV-infected MSM.

Results: Eight men with acute HCV underwent SGS of their plasma virus RNA from the earliest available visits. All had precise and unambiguous identification and enumeration of transmitted HCV genomes. Six of 8 men were productively infected by single HCV genomes; none had rectal bleeding associated with sex nor were they exposed to blood of others; one had injected methamphetamine but without sharing injection equipment, and then had sex. Two men were infected by >10 genomes; one had shared injection equipment and then had sex, and the other denied any injection, rectal trauma, or bleeding with sex. None had an intermediate number of infecting genomes.

Conclusions: Most HCV infections of HIV-infected men were caused by a single transmitted virus, suggesting that HCV infection of MSM is due to a limited exposure to infecting virus across a relatively intact mucosal barrier. In contrast, the one man who had shared injection equipment was infected by a high number of viruses. These patterns of HCV infection parallel both sexual and parenteral acquisition of HIV, where most infections are caused by a single versus a higher number of transmitted HGV genomes, respectively. Larger prospective risk factor studies are needed using SGS to provide novel epidemiological insights to better characterize HCV acquisition in HIV-infected MSM.

675  **Higher Risk of Sexually Acquired HCV Coinfection in MSM With Wide HIV Transmission Bottleneck**

Roger D. Kouyos1, André Rauch1, Dominique Braun1, Sabine Yetly1, Jürg Böni1, Thomas Klimek1, Vincent Aubert1, Bruno Ledergerber1, Huldrych Günthard1, The Swiss HIV Cohort Study (SHCS)

1University Hospital Zurich, University of Zurich, Zurich, Switzerland, 2Inselspital Bern, Bern, Switzerland, 3University of Geneva, Geneva, Switzerland, 4University of Zurich, Zurich, Switzerland, 5University of Basel, Basel, Switzerland, 6University of Lausanne, Lausanne, Switzerland

Background: Even though the mechanisms responsible for the recent dramatic increase of sexually transmitted HCV among HIV-infected MSM remain largely unknown, an important contribution by high-risk sexual behaviors has been suggested. At the same time such high-risk behaviors have been linked with a broad transmission bottleneck in HIV as they might lead to mucosal breaches, which could facilitate the transmission of several genetically distinct viruses in one transmission event.

Methodology: We assessed the association between the width of the HIV transmission bottleneck and the incidence of HCV coinfections in HIV-infected MSMs from the Swiss HIV Cohort Study. As a proxy for the width of the transmission bottleneck we used the fraction of ambiguous nucleotides in Genotypic Resistance Tests (GRT) from recently infected MSMs. We have previously shown that a high fraction (>0.5%) of ambiguous nucleotides during recent infection corresponded to a high viral diversity, which in turn indicated a broad transmission bottleneck. Accordingly, the HIV transmission bottleneck was considered to be broad if the fraction of ambiguous nucleotides exceeded 0.5% in GRTs from recent (less than one-year-old) infections and narrow otherwise. Recent infection was determined by Acute Retroviral Syndrome and by negative and positive HCV-serology less than 1 year apart. The impact of the HIV-transmission bottleneck on HCV incidence was quantified as Hazard Ratios (HR) determined from uni- and multivariable Cox-proportional hazards models.

Results: We considered 543 MSMs, who were HCV-negative at baseline and for which a GRT sampled during recent infection (<1 year post seroconversion or ARS) was available. Of those individuals, 119 (21.9%) exhibited a broad transmission bottleneck and 22 (4.1%) had an incident HCV infection. The total incidence rate of HCV infections was 7.6/1000 person-years. Individuals with a broad HIV-transmission bottleneck exhibited an overall fourfold higher hazard of an incident HCV infection than individuals with a narrow HIV transmission bottleneck (HR[95%CI]=4.7[2.0,10.8] , p<0.001). This effect remained robust when adjusting for time (year of enrolment), geography (lab performing the GRT), and age: in the corresponding multivariable model the hazard of an HCV coinfection was increased by an HR of 4.8[2.0,11.4] if the HIV-transmission bottleneck was broad.

Conclusions: Our results indicate that the currently occurring sexual spread of HCV is focused on those MSMs that are also prone to exhibit a broad transmission bottleneck at HIV transmission. This suggests high-risk behavior and mucosal barrier impairment may play an important role in the sexual transmission of HCV.

676  **Seminal HCV RNA Level May Mirror Dynamics of Plasma HCV RNA in HIV-Positive Men With Acute HCV**

Daniel Bradshaw1, Francois Lamoury1, Beth Catlett2, Tanya L. Applegate1, John Mcallister2, Gregory J. Dore1, Gail Matthews1, Mark Danta3

1Kirby Institute, University of New South Wales, Sydney, Australia, 2St Vincent’s Hospital, Sydney, Australia, 3Faculty of Medicine, University of New South Wales, Sydney, Australia

Background: We hypothesise that sexual transmission of HCV in HIV-positive men who have sex with men may be due to raised semen HCV RNA in acute or recent HCV (AHCV) infection.

Methodology: The M2000 RT-PCR was optimised for quantification of HCV RNA in semen with lower limit of detection of 60 IU/mL. Men with AHCV (duration <12 months) or chronic HCV (CHCV, >12 months) not on anti-HCV therapy were prospectively recruited. An STI screen was performed. Paired semen and EDTA plasma samples were assayed for HCV RNA. Data were analysed with Chi2, Fishers Exact, Mann-Whitney U and Kruskal-Wallis tests.

Results: Of 66 HCV RNA-positive men, median age 49, IQR 44-53 years, 18 (27.3%) were infected with AHCV/HIV, 22 (33.3%) CHCV/HIV and 26 (39.4%) CHCV. In men with AHCV, median duration of infection was 3.5, IQR 2.0-6.3 months. Of 40 HIV-positive men, 35 (87.5%) were on antiretrovirals with undetectable plasma HCV RNA; median CD4 count was 598, IQR 410-788 cells/mm³. HCV genotypes were 1a (38, 57.6%), 1b (5, 7.6%), 3a (18, 27.2%), other (5, 7.6%). Semen HCV RNA was detected in 29/66 (43.9%) men at baseline. There was a similar proportion of men with detectable semen HCV comparing AHCV with CHCV (p=0.613), or HIV-positive with -negative (p=0.191). Median plasma HCV RNA was 6.1, IQR 5.5-6.5 log IU/mL and not significantly different comparing AHCV/HIV, CHCV/HIV and CHCV (p=0.055). When detected, median semen HCV RNA was 2.1, IQR 1.8-2.6 log IU/mL. HCV RNA levels in semen and plasma were correlated (r²=0.142). Median plasma HCV RNA was higher in men with detected versus undetected
semen HCV RNA for AHCV/HIV (6.2, IQR 6.0-6.7 versus 4.6, IQR 3.2-5.7 log IU/mL p=0.001) but not for CHCV/HIV or CHCV (Fig. 1). Of 35 men attending a follow up visit (at median 18, IQR 15-26 weeks), semen HCV RNA was detected for 26 (74.3%) in 1 sample, including for 12 (34.3%) in both. Median plasma HCV RNA was higher in men with 2 samples positive (p=0.009). Presence of STI was not significant for shedding (p=0.271).

Conclusions: Semen HCV RNA was detected in 43.9% of men at baseline, at median 4.0 log IU/mL less than plasma. In 40.0% of men followed up, shedding was intermittent. For men with AHCV/HIV, detectable semen HCV RNA was more likely with higher plasma HCV RNA, implying a possible relationship between HCV dynamics in plasma and semen in the acute phase. If, as previously described, HIV-coinfected individuals in early acute HCV have a higher plasma HCV RNA, this could lead to raised semen levels, facilitating sexual transmission.

677 HCV Viral Load Kinetics During Acute Hepatitis C in HIV-Infected Patients: A Model-Based Analysis
Romain Ragonnet1, Christoph Boesecke1, Marguerite Guiguet1, Karine Lacomb3,1, Jeremie Guedj1, Jürgen K. Rockstroh2, Yazdan Yazdanpanah1,4, Sylvie Deuffic-Burban1,7
1INSERM U1137, Paris, France, 2Department of Internal Medicine I, Bonn University Hospital, Bonn, Germany, 3INSERM U943, Paris, France, 4INSERM UMR S 707, Paris, France, 5Service de Maladies Infectieuses et Tropicales, Hôpital Saint-Antoine, Paris, France, 6Service des Maladies Infectieuses et Tropicales, Hôpital Bichat Claude Bernard, Paris, France, 7INSERM U995, Lille, France

Background: The timing of treatment initiation in case of acute hepatitis C (AHC) occurrence is unclear. Indeed, patients may have spontaneous clearance (SC) but time at which SC may occur is imprecise since infection can rarely be dated. Besides, no study explored the relationship between viral kinetics and chance to achieve SC. Objectives of this study are first to model HCV viral load kinetic during the acute phase of hepatitis C in HIV-infected patients in the absence of HCV treatment; and second to use this model to determine frequency of SC occurrence over time, in order to help physicians in treatment decision making.

b) Different profiles identified during the drop phase

c) Cumulative frequency of SC over time among spontaneous clearers
Methodology: Based on available medical literature, we considered four phases for HCV RNA kinetic during AHC: ramp-up, plateau, drop and stabilization; the two last phases being different according to whether the patient is a spontaneous clearer (SC) or a chronic evolver (CE). We first characterized each phase using individual HCV RNA data from 261 HIV-HCV co-infected patients in acute phase of HCV where 33% of untreated patients were SC, and using data available in the literature. For each phase, random distributions were determined and Kolmogorov-Smirnov and Shapiro-Wilk tests were used to provide reliability. Second, we simulated the trajectory of 50,000 virtual patients to obtain cumulative frequency of SC over time. Time of SC occurrence is defined as first undetectable HCV RNA.

Results: Data were fitted according to distributions and estimated parameters reported in the table (Figure a). For the drop phase, we identified five different profiles: four for CE (CE1 to CE4) and one for SC (Figure b). The model estimated a median time from infection to SC occurrence of 187 days (IQ 130–263); no SC was observed before 35 days and 10% occurred after one year (Figure c).

Conclusions: This model brings knowledge about time of SC occurrence. It also highlights the diversity of HCV viral loads evolution profiles after infection in HIV-infected individuals. These predictions could help optimize the timing of treatment initiation during acute hepatitis C.

Background: Effective immune responses against hepatitis C virus (HCV) are dependent on CD8+ T cells, yet their function is impaired in chronic infection, which is also a feature of chronic HIV infection. HCV is the most prevalent co-morbidity in HIV, yet the effect of HCV on HIV infection remains largely unknown. This study will determine how CD8+ T cell activity (specifically IL-7 activity) is impaired in chronic HCV infection. IL-7 is critical for CD8+ T cell development, and important for T cell homeostasis, memory cell generation, and cytolytic function. CD8+ T cell responses to IL-7 are dependent on the expression of IL-7 receptor alpha on the cell membrane (mCD127). Reduced mCD127 expression, increased plasma soluble CD127 (sCD127) levels, or cellular deficiencies in IL-7 signalling may contribute to impairment, as we reported in HIV infection. The hypothesis of this study is that HCV infection decreases CD8+ T cell activity, specifically IL-7 responsiveness, in both HCV and HIV-HCV infection.

Methodology: CD8+ T cells were isolated from healthy donors (controls) as well as individuals with untreated HCV infection and HAART-controlled (< 40 copies/ml HIV RNA) HIV-HCV co-infection. Expression of mCD127 on CD8+ T cells and plasma sCD127 levels were measured by flow cytometry and immunobead assays, respectively. IL-7 induced signalling (STAT5 phosphorylation), proliferation, and production of the anti-apoptotic molecule Bcl-2 were measured by flow cytometry. Dose responses were assessed by regression analysis (P < 0.05).

Results: There was no significant difference in mCD127 expression on blood-derived bulk CD8+ T cells or plasma sCD127 levels between control, HCV and HIV-HCV infection. IL-7-induced STAT5 phosphorylation was significantly reduced (p = 0.005) in CD8+ T cells from HCV infection compared to controls, and similar to HIV-HCV co-infected individuals. Cell division of CD8+ T cells cultured with suboptimal amounts of T cell stimulator (PHA) was of lower magnitude in HIV infection than controls. Lastly, the production of Bcl-2 in response to IL-7 was significantly reduced in CD8+ T cells of HCV and HIV-HCV infected individuals compared to controls (p<0.001 and 0.04, respectively).

Conclusions: These results suggest that CD8+ T cell impairment in HCV infection is characterized by decreased responsiveness to IL-7, independent of mCD127 expression, in contrast to what is observed in HIV infection. The mechanism of CD8+ T cell impairment may be through IL-7-stimulated signalling, since we know Bcl-2 production is STAT5 dependent. Identifying the mechanisms of CD8+ T cell impairment in HCV infection has implications in the design of novel treatments, namely cytokine directed immunotherapies, to help reduce the burden of HCV effects on HIV infection.

679 HCV and GBV-C NS5A Proteins Inhibit TCR-Mediated Activation of Human CD4+ T Cells
Nirjal Bhattarai, Bennett E. Thompsona, James H. McLinden, Jinhua Xiang, Jack T. Stapleton
University of Iowa and Iowa City VA, Iowa City, IA, United States

Background: Hepatitis C virus (HCV) and GB virus C (GBV-C) are closely related members of the family Flaviviridae, and both viruses are capable of establishing persistent infection. In clinical studies, HCV and GBV-C infections are characterized by reduced immune activation, delayed antibody response and altered T cell function. Although T cells are not the primary site of HCV replication, numerous studies demonstrate the presence HCV RNA in T cells and there is some evidence of viral replication in these cells. Previously, we demonstrated that the GBV-C envelope protein E2 inhibits T cell receptor (TCR) signalling and contributes to reduced immune activation by competing for activation of the lymphocyte-specific protein tyrosine kinase (Lck). Here, we studied the effects of HCV and GBV-C NS5A protein on T cell activation.

Methodology: Previously described Jurkat cell lines stably expressing HCV and GBV-C NS5A protein were studied. TCR signalling was monitored by measuring IL-2 release (ELISA) and CD69 expression by flow cytometry after stimulation with anti-CD3/CD28 or PMA-ionomycin. The effect of MSD HCV NS5A inhibitor on the NS5A-mediated modulation was examined.
Poster Abstracts

**Results:** T cell activation was inhibited in Jurkat cells expressing either HCV or GBV-C NS5A protein following TCR stimulation with anti-CD3/soluble CD28 when compared to controls (p<0.01 for both IL-2 release and CD69 upregulation). Maintenance of cells in the presence of a potent NS5A inhibitor (provided by Merck) rescued HCV NS5A-mediated TCR inhibition, but not GBV-C NS5A-mediated TCR inhibition following TCR stimulation (IC₅₀ ~ 2.5μM; See Figure). NS5A proteins inhibited TCR-signaling upstream of NFAT and PKC activation, as PMA-ionomycin-mediated activation was not inhibited by HCV or GBV-C NS5A.

**Conclusions:** TCR signaling pathways are modulated by HCV and GBV-C NS5A protein expression in vitro. The HCV NS5A inhibitor blocked the TCR signaling defect induced by NS5A for HCV, but not GBV-C, thus this molecule appears specific for the HCV-NS5A protein, despite considerable amino acid sequence and predicted structural homology with GBV-C NS5A. Studies are underway to characterize the mechanism(s) by which HCV and GBV-C NS5A reduces TCR signaling. Since TCR activation is required for T cell proliferation and function during viral infection; these data may provide insight into HCV and GBV-C pathogenesis and persistence.

**680 Impact of HCV Coinfection On T-Cell Dynamics in Long-Term HIV Suppressors Under cART**

Olivia Zaegel¹, Sylvie Bregione¹, Carla E. Cano¹, Véronique Obry-Roguet¹, Corinne Nicolin-Brunet², Catherine Tamalet¹ ³, François Dignat-George⁴, Isabelle Poizot-Martin⁵ ⁶

¹Immuno-Hematological Clinical Unit, Aix Marseille University, APHM, Sainte Marguerite Hospital, Marseille, France, ²Service d’Hematologie et de Biologie Vasculaire, Aix Marseille University, APHM, Conception Hospital, Marseille, France, ³Fédération de Microbiologie Hospitalière, Aix Marseille University, APHM, Timone Hospital, Marseille, France, ⁴UMR 6236, Marseille, France, ⁵INSERM U912 (SESSTIM), Marseille, France

**Background:** HCV co-infection affects a fifth of HIV-infected subjects in the western world. The benefit provided by the cART revolution in HIV care is challenged by the eventual drawbacks inherent to the hepatitis C pathology. The full extent of HCV impact on the evolution of T cell compartments in patients that achieve long term HIV-suppression under cART is yet to be determined.

**Methodology**: A prospective study performed in an out-door HIV care unit following 1495 HIV-infected patients. Data of patients that achieved undetectable HIV load for at least 3 years were collected retrospectively from the Nadis® electronic database from January 1997 to April 2005. This period was defined in order to select patients that were naïves of IFN-based hepatitis treatment. T cell counts were assessed from the first undetectable HIV load and every 6 months during the study period.

**Results:** Screening yielded data of 356 long term HIV suppressors, of which 130 were HCV co-infected. Most patients were male with median age of 36y for HCV coinfected vs 39 y (p=0.001). Median follow-up for HIV was longer in HCV coinfected (10y vs 4 y, p<0.001). CART regimens were no different between the two groups. As shown in the figure, HIV-infected (group 1) and HCV co-infected patients (group 2) displayed similar positive patterns of reconstitution of CD4 counts, though the mean fraction of CD4 cells was slightly higher in group 1 (30.3±1.1 vs. 27±1.1% after 3 yrs in groups 1 and 2, respectively, p<0.001). Regarding CD8 cells, HIV suppression led to a modest drop of median CD8 counts in group 1 (p=0.027), but not in group 2. More strikingly, group 2 displayed higher mean CD8 counts compared to group 1 (mean diff. = 135.71 ± 26.89 CD8/mm3, p<0.001).
681 CD3+CD56+ Natural Killer-Like T Cells in HIV(+ ) Patients With Acute Hepatitis C

Pavlos Kokordelis1,2, Benjamin Krämer1,2, Christoph Boesecke1,2, Esther Voigt1, Patrick Ingliz4, Andreas Glässner1,2, Ulrich Spengler1,2, Jürgen Rockstroh1,2, Jacob Nattermann3

1Internal Medicine I, University of Bonn, Bonn, Germany, 2German Center for Infection Research (DZIF), Bonn, Germany, 3Internal Medicine I, Praxis am Ebertplatz, Cologne, Germany, 4Medical Center for Infectious Diseases (MID), Berlin, Germany

Background: In Western Europe and the US approximately 30% of HIV (+) patients are co-infected with the hepatitis C virus (HCV), which has become a major cause of morbidity and mortality in HIV(+ ) patients.

We recently showed that natural killer cells are able to recognize HCV-containing target cells via the NK cell receptors NKG2D and Nkp46 and to effectively block HCV replication in vitro. Moreover, we presented first data suggesting NK cells to critically affect outcome of acute hepatitis C in HIV(+) patients.

CD3+CD56+ natural killer-like T cells represent a subset of T lymphocytes that also express natural killer cell receptors.

Methodology: 36 HIV(+) patients with acute hepatitis C, including 13 patients with spontaneous clearance and 23 patients that subsequently developed chronic hepatitis C, were studied. As a control HIV mono-infected patients (n=8), HIV(+) patients with chronic hepatitis C (n=12), HIV(+) patients with chronic HCV infection (n=8) as well as 12 healthy individuals were analyzed. Peripheral NKT cells (CD3+CD56+) were phenotypically analyzed by flowcytometry. IFN-γ secretion and anti-HCV activity of NKT cells were analyzed using the HuH7A2 HCV replicon system.

Results: Frequency of CD3+CD56+ NK-like T cells did not differ significantly between the study groups.

However, we observed a significant higher expression of the maturation markers CD27, CD127, and CD161 on CD3+CD56+ NK-like T cells in healthy controls than in HIV mono-infected patients and HIV patients with an acute HCV infection, respectively.

Interestingly, CD3+CD56+ NK-like T cells from HIV patients with acute hepatitis C displayed a higher expression of CD69, indicating a more activated status as compared to healthy controls. Of note, a high CD69 expression was associated with spontaneous clearance of acute hepatitis C, suggesting a role for CD3+CD56+ NK-like T cells in anti-HCV immune responses.

Accordingly, we found IL12/IL15-activated CD3+CD56+ NK-like T cells to effectively block HCV replication in an IFN-γ dependent fashion. However, CD3+CD56+ NK-like T cells from HIV patients with acute HCV infection displayed a significantly impaired capacity to secrete IFN-γ compared to both HIV mono-infected as well as healthy individuals.

Conclusions: Our results indicate that CD3+CD56+ NK-like T cells have the potential to block HCV replication but are functionally impaired in HIV(+) patients with acute hepatitis C.

682 The Effect of Hepatitis C (HCV) Clearance On Macrophage Activation in HIV/HCV Coinfection

Kara W. Chew1, Lei Hua2, Debika Bhattacharya2, Adedot A. Butt1, Martha Lewis1, Raymond T. Chung1, Janet W. Andersen2, Martha S. Currier1

1David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, United States, 2Harvard School of Public Health, Boston, MA, United States, 3University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 4Harvard Medical School, Boston, MA, United States

Background: Macrophage activation may contribute to accelerated atherosclerosis in HIV-infected persons. We hypothesized that HCV coinfection increases macrophage activation and cardiovascular disease (CVD), and that successful HCV treatment in coinfected persons reduces CVD risk through reduction in macrophage activation.

Methodology: Of 54 coinfected subjects who received up to 72 weeks of pegylated interferon/ribavirin (PEG/RBV), 27 with and 27 without sustained virologic response (SVR, HCV RNA<60 IU/mL 24 weeks after end of treatment [EOT]) matched by race/ethnicity and sex, stored plasma before treatment and 24 weeks after EOT were tested for soluble CD14 (sCD14) and CD163 (sCD163). Baseline characteristics and biomarkers were compared between SVRs and non-SVRs by Fisher’s exact and Wilcoxon tests and associations between biomarkers and baseline variables by simple regression. Changes in each biomarker were examined within and between groups by t-test and regression models adjusting for race/ethnicity, sex, and with backward selection of baseline variables significant at 0.10 level (HCV RNA, fibrosis stage, HCV treatment history, AST and ALT level) (Model 1), and further controlling for change in ALT (Model 2) and PEG/RBV duration (Model 3).

Results: Of 54 subjects, 30 white, 24 black, and 44 male, 78% had HIV-1 RNA<50 copies/mL. Median [Q1, Q3] CD4 was 544 [370, 734] cells/μL. 3 SVR and 4 non-SVR subjects had baseline CVD; none had a CVD event on study. The Table describes baseline and change in markers. Baseline sCD163 was associated with fibrosis stage (P<0.001) and baseline ALT (P<0.001). Controlling for fibrosis, there was no difference in baseline sCD163 by SVR status (P=0.094). In Model 1 adjusting for race/ethnicity, sex and baseline AST after backward selection, SVR was associated with decrease in log10 sCD163 (p=0.042), but not after further adjusting for change in ALT (Model 2, P=0.096, change in ALT P=0.002) or PEG/RBV duration (Model 3, P=0.071, PEG/RBV P=0.052).
**HIV Patients Develop High Levels of Broadly Neutralizing Antibodies Against Hepatitis C Virus**

Quentin Lepiller1,2, Catherine Faurelle1, Laura Heydmann1, Christiane Moog1, David Rey1, Olivier Lambotte1, Nicolas Meyer1,2, Heidi Barth1,2, Françoise Stoil-Keller1,2, Samira Fafi-Kremer1,2

**Background:** Hepatitis C virus (HCV) infection is a major health issue for HIV-infected patients. The high cost of new direct-acting antivirals against HCV limit their use in countries with poor income, underscoring the urgent medical need of an HCV vaccine. The impact of HIV infection on the HCV-humoral response remains unknown although it might greatly influence the design and the effectiveness of an HCV vaccine in HIV-infected patients. The aim of this study is to analyze the HCV-specific neutralizing response in HIV-infected patients.

**Methodology:** HCV-specific neutralizing antibody-mediated response was assessed in a cohort of 299 patients including 136 HIV-/HCV+, 70 HIV+/HCV-, and 63 HIV+/HCV+. Thirty healthy HCV-unexposed controls were used to define neutralization assay cutoff. Neutralization experiments were performed with patients’ sera and purified immunoglobulins G (IgG) using HCV pseudoparticles (HCVpp) and cell-culture derived HCV (HCVcc) model systems.

**Results:** Mean age of HIV-/HCV+ and HIV+ patients was 49 and 43 years, respectively. Sixty-five (49%) HIV+ patients have detectable HCV RNA in plasma with a mean viral load at 3.96 (1.72-5.83) log10 copies/mL. Mean CD4+ cell count in all HIV+ patients were 490 (41-1770) cell/mm3. HCV RNA was detectable in 70% of HIV-/HCV+ and 57% of HIV+/HCV+ patients, with a mean HCV RNA load at 5.96 (4.38-7.15) and 5.83 (1.51-7.24) log10 copies/mL, respectively (p=0.59). High levels of neutralizing antibodies (nAbs) were detected in 97% of HCV-viremic HIV+/HCV+, among them 69% harbored nAbs against the three HCVpp genotypes 1a, 1b, and 3a, similarly to HCV-viremic HIV-/HCV+ patients (95% and 65%, respectively, p>0.05). In HCV-aviremic patients, high levels of nAbs were more frequently noticed in HIV+/HCV+ (85% against at least one genotype and 15% against the three genotypes) than in HIV-/HCV+ individuals (44% and 7%, respectively, p<0.001). Moreover, broadly nAbs anti-HCV were detected in 13% of HIV+/HCV- individuals. All the data were confirmed using HCVcc model system. No correlation was observed between nAbs and HIV RNA load or CD4+ cell count.

**Conclusions:** Our results indicate that HIV-infected patients are able to develop high levels of HCV-specific broadly nAbs. Persistence of nAbs in HCV-aviremic HIV+/HCV+ and the detection of neutralizing activity in HIV+/HCV- patients suggest that they may have experienced frequent exposure to HCV as observed in HIV-negative individuals (e.g injection drug users) with the immune capacity to clear HCV. These data suggest that HCV-humoral response is not impaired during HIV-infection. The persistence of a broad HCV-neutralizing response in HIV+ patients may forecast promising achievement of HCV vaccination in HIV-infected persons.

---

**Analysis and Senescence Markers in HCV-Infected Patients On PegIFN/RBV/Telaprevir Tritherapy**

Isabelle Pellegrin1, Céline Cognet1, Pascale Trimoulet1, Juliette Foucher1, Julien Vergniol1, Wassil Mermouche2, Jean-Luc Taupin1, Linda Wittkop1, Jean-François Moreau1, Victor de Ledinghen1,2

1Immunology, Bordeaux Hospital, Bordeaux, France, 2Virology, Bordeaux Hospital, Bordeaux, France

**Background:** Immune activation and senescence described in chronic viral infections is associated with an increase in morbidity and mortality. No data were reported in HCV-infected patients (pts). We describe the immunological markers of activation, senescence and exhaustion in pts initiating PegIFN/RBV/Telaprevir tritherapy.

**Methodology:** Pts with a prior PegIFN/RBV failure who initiated tritherapy (D0) and obtained SVR24 were included. CD4 and CD8 activation (DR+), maturation (naive, memory T cells), senescence (CD57+CD28-), regulatory T cells, and PD1+T cells were measured at D0, W12, W48 and W52-72. Kinetics was described during the 3 periods: D0-W12 tritherapy; W12-W48 bitherapy; W48-W72 off treatment. DO data were compared with 20 healthy donors (HD).

**Conclusions:** SVR was associated with decrease in plasma sCD163 but not sCD14 levels. Adjustment for change in ALT attenuated the association between SVR and sCD163, suggesting hepatic inflammation may mediate this association. HCV treatment may reduce hepatically-driven macrophage activation, with greater sensitivity of sCD163 as compared to sCD14 to hepatic inflammation. Degree of liver disease must be considered in the interpretation of macrophage activation markers in HCV-infected persons.
Results: 83 pts were included: 66% males, median age=57 years, infection duration=30 years, HCVRNA=1643000 IU/mL, fibroscan =10 kPa (36% F4). There is no significant difference for CD4+ and CD8+ senescence or maturation between pts at D0 and HD. CD4+ and CD8+ activation was higher in patients (p=10-3 and 0.07) than in HD, although within the normal range. D0-W12 period: significant decrease in senescent (P =10-4) and memory cells (P=10-2 to 10-4) without variation in activated CD4+ and CD8+; increase in Treg (P=10-3) without variation in % PD-1+CD4+ or CD8+. W12-W48 period: No variation occurred. W48-W72 period: increase in memory (P<10-4 to P<10-2), senescent (P=10-2) and activated (P<10-4) CD4+ and CD8+, while naive T cells decreased (P<10-4).

Conclusions: Chronic HCV replication for more than 30 years is associated neither with a CD8+ clonal expansion, nor with lymphocyte activation or senescent status in the peripheral blood. No association was found between activation and fibrosis. We speculated that the immunological variables kinetics on successful IFN-based therapy may be due to variations in lymphocytes homing: decrease in memory and senescent lymphocyte subsets on suppressive tritherapy, increase in memory, senescent and activated lymphocytes after the end of IFN exposure without detectable HCV. The intrahepatic immune response does exist and may be under the regulation of lymphocytes and Treg homeostasis. It seems relevant to follow the persistence of this activated status at the end of IFN exposure and to evaluate its clinical impact, notably in terms of fibrosis evolution and comorbidities. This observed immune paradox may be of interest for the deciphering of new (IFN-free) therapeutic strategies.

---

**HCV Viremia and the Risk of Acute Myocardial Infarction at Various Lipid Levels**

Adeel A. Butt 1,2, Kara W. Chew1, Kathleen Corey1, Raymond T. Chung2, Jawed Butler2, Kenneth E. Sherman4, Matthew S. Freiberg1, Sebhat Erqou7

1University of Pittsburgh School of Medicine and VA Pittsburgh Healthcare System, Pittsburgh, PA, United States, 2Sheikh Khalifa Medical City, Abu Dhabi, United Arab Emirates, 3David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, United States, 4Harvard Medical School and Massachusetts General Hospital, Boston, MA, United States, 5Emory University, Atlanta, GA, United States, 6University of Cincinnati, Cincinnati, OH, United States, 7Weill Cornell Medical Center, New York, NY, United States

**Background:** Studies have shown an association between HCV infection and cardiovascular disease (CVD) events. The role of HCV viremia upon the risk of acute myocardial infarction (AMI) at varying lipid levels is unknown.

**Methodology:** We used Electronically Retrieved Cohort of HCV Infected Veterans (ERCHIVES) to determine the risk of AMI at various lipid levels for HCV antibody positive persons with detectable and undetectable HCV RNA. All subjects were HCV treatment naïve. We excluded females (due to small numbers), smokers, and those with HIV, diabetes, prior cardiovascular disease, chronic kidney disease, chronic obstructive lung disease or hypertension at baseline. Lipid categories were based on National Cholesterol Education Program risk profile levels. Risk of AMI by lipid level was determined by Cox regression analyses.

**Results:** We compared 5,979 HCVRNA+ and 167 HCVRNA- subjects. After adjusting for age, race, body mass index and other lipids, the risk of AMI was progressively higher with higher total cholesterol, LDL-cholesterol and triglyceride levels among HCVRNA+ subjects, while the association among HCVRNA- subjects was not statistically significant at any level. (Table) At the highest levels within the lipid category, the risk of AMI increased between 22-64% compared with desirable levels.

**Conclusions:** In HCV viremic subjects, higher lipid levels were associated with higher risk of AMI. This association was not seen in non-viremic persons, possibly due to small sample size with few incident AMI events. The effect of lipid lowering therapy and viral eradication through HCV therapy upon the risk of future AMI needs further study.
### Association of Coinfection With HBV, HCV, or Both On Survival Among HIV-Infected Adults

Tanyaporn Wansom, Catherine G. Sutcliffe, Shruti H. Mehta, Carleigh L. Benton, Richard C. Moore, David T. Thomas, Mark S. Sulkowski

**Infectious Diseases, Johns Hopkins University SOM, Baltimore, MD, United States, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States**

**Background:** HBV and/or HCV coinfection is associated with increased morbidity and, in some studies, with increased mortality in HIV-infected patients. The impact of antiretroviral therapy (ART) on this relationship is incompletely defined. We examined survival among adults who were infected with HIV alone or in conjunction with HBV, HCV, or both in the era of tenofovir containing ART.

**Methodology:** We used data from a prospective clinical cohort of 1603 patients with HIV and known HBV and HCV status receiving care at the Johns Hopkins HIV Clinic from January 2002 to March 2012. Chronic HBV infection was defined as a single HBsAg positive result. HCV infection was defined as HCV antibody positive or detectable HCV RNA. The primary outcome was all-cause mortality rates per 1000 person years according to infection status: HIV alone (n=844), HBV/HIV (n=67), HCV/HIV (n=652) and HCV/HBV/HIV (n=40).

Multivariable negative binomial regression was performed.

**Results:** At enrollment, patients with HCV alone or with HBV were older (median age, 45 years vs. 40 years), had lower CD4 cell count (median 349/mm^3 vs. 443/mm^3), and were more likely to have a history of injection drug use (73% vs. 8%) than those with HIV alone. Patients with HBV alone were similar to those with HIV alone. Crude mortality rates (per 1000 person-years) were higher in patients with HBV/HIV (45.7, 95% CI 25.9-80.4), HCV/HIV (45.6, 95% CI 28.7-66.8), and HCV/HBV/HIV (45.8, 95% CI 28.7-66.8) compared to HIV alone (41.9, 95% CI 32.3-52.9). After multivariable adjustment, the hazard ratio for mortality in HBV/HIV, HCV/HIV, and HCV/HBV/HIV was 1.40 (95% CI 1.01-1.93), 1.45 (95% CI 1.04-2.01), and 1.42 (95% CI 1.04-1.95), respectively.

**Figure 1.** Cumulative Survival After Clinic Enrollment
Incidence Rates and Risk Factors for Severe Bacterial Infections in HIV/HCV-Coinfected Patients

Kathleen C. Rollet 1, John Gill 1, Curtis Cooper 1, Mark Hull 1, Joseph Cox 1, Bryan Conway 1, Neora Pick 1, Marie-Louise Vachon 1, Marina B. Klein 1

1Division of Infectious Diseases and Chronic Viral Illness Service, McGill University Health Centre, Montreal, QC, Canada, 2Southern Alberta HIV Clinic, Calgary, AB, Canada, 3The Ottawa Hospital – General Campus, Ottawa, ON, Canada, 4BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 5Montreal General Hospital, Montreal, QC, Canada, 6Vancouver Infectious Diseases Research and Care Centre, Vancouver, BC, Canada, 7Oak Tree Clinic, Vancouver, BC, Canada, 8Centre Hospitalier Universitaire de Quebec, Quebec, QC, Canada

Background: HIV/HCV co-infection is placing an increasing burden on the health care system. Due to comorbidities and more rapid progression of liver disease associated with co-infection, infectious complications may contribute to excess morbidity. We measured the incidence and identified predictors of severe bacterial infections requiring health service use or leading to death among HIV/HCV co-infected patients.

Methodology: Data were analyzed from a Canadian multicentre prospective cohort of 1151 HIV/HCV co-infected patients with at least 2 consecutive visits between 2003-13. Every 6 months, patients self-reported reasons for walk-in clinic and emergency room visits and overnight hospitalizations. Causes of death were available from detailed case reports and linkage to vital statistics. The primary outcome was a first episode of severe bacterial infection (overall). We also examined specific subgroups: pneumonia, invasive bacterial infections [osteomyelitis, endocarditis, peritonitis, pyelonephritis, bacteremia, meningoencephalitis, septic arthritis] and skin and soft tissue (SST) infections. We used discrete-time proportional hazards models adjusted for age, sex, baseline BMI (as a marker for risk of insulin resistance) and hemoglobin and time-updated intravenous drug use (IDU), cigarette smoking, CD4 cell count, HIV-RNA and APRI (≥1.5=significant fibrosis).

Results: At baseline, median age was 45 years, 26% were female, 16% Aboriginal, 35% active IDU, 76% smoked cigarettes and median BMI was 24. Median CD4 was 440 cells/μL and 81% were on cART. During 2063 person-years (PY) of follow-up, 113 (13%) patients reported any severe bacterial infection [IR=5.5/100 PY; 95% CI, 4.5-6.5]. 61 (7%) developed at least one episode of pneumonia [IR=2.9; 2.1-3.6], 26 (3%) invasive infection [IR=1.2; 0.7-1.6], and 37 (4%) SST infection [IR=1.7; 1.2-2.2]. Of 133 deaths, 13 (10%) were attributable to infection. Factors associated with severe bacterial infections are shown in the table below. Inclusion of HCV therapy in the models had no effect on the results.

Conclusions: Severe bacterial infections represent common causes of death and health service use among HIV/HCV coinfected patients. Risk for these infections is driven primarily by low CD4 and IDU rather than stage of liver disease. Insulin resistance and anemia may also be contributory. Efforts to address comorbidities and improve ART uptake and adherence in this population are warranted to limit the burden of severe infections.

Note: Sample size varies by outcome as risk set of 2 consecutive visits were necessary for the analysis.
**Methodology:** We conducted a retrospective cohort study using the databases of Electronically Retrieved Cohort of HCV Infected Veterans (ERCHIVES). HCV and HIV infections were ascertained using antibody testing at baseline. CVD data was obtained using ICD-9 codes as per our previously published work, and outcomes studied included: AMI, congestive heart failure (CHF), stroke, peripheral vascular disease (PVD) and venous thromboembolism (VTE). Multivariate Cox-regression models were used to determine the risk of CVD outcomes among veterans with HIV/HCV co-infection compared to those without HIV or HCV infection. Adjustment was made for traditional CVD risk factors.

**Results:** Among the HCV+ Veterans, 2620 (1.3%) individuals had HIV infection, while among the HCV− Veterans, 4896 (2.4%) had HIV infection. Veterans with HIV/HCV co-infection, compared to those without HIV or HCV infection were younger (mean age 50 vs 53 years), were more likely to be Blacks (59% vs 29%), and smokers (20% vs 17%). They were less likely to have diabetes (13% vs 16%), had lower body mass index (BMI, 25 vs 29 kg/m²), and low-density lipoprotein (LDL) cholesterol (91 vs 117 mg/dl) (p-value<0.0001, for all comparisons). The hazard ratios (95% confidence intervals) for MI, stroke, CHF, PVD and VTE for veterans with HIV/HCV co-infection compared to those without HIV or HCV infection, after adjustment for age, sex, smoking, diabetes, and BMI were 1.24 (1.01-1.51), 1.59 (1.25-2.03), 2.05 (1.69-2.48), 1.19 (0.99-1.44), and 2.35 (1.19-4.61), respectively. The corresponding HRs (95% CIs) after further adjustment for LDL-cholesterol, high-density lipoprotein cholesterol and triglycerides were 1.14 (0.94-1.40), 1.53 (1.20-1.95), 1.87 (1.55-2.26), 1.12 (0.93-1.35) and 2.46 (1.24-4.85), respectively.

**Conclusions:** In a retrospective cohort study of HCV+ and HCV− veterans, individuals with HIV/HCV co-infection had increased risk of stroke, CHF and VTE compared to those without HIV or HCV infection, after adjustment for traditional CVD risk factors.

</tbody>
</table>

Model 1 – age, sex
Model 2 – Model 1+ smoking history, diabetes history, body mass index
Model 3 – Model 2+ LDL-c, HDL-c, triglycerides
MI- myocardial infarction; CHF - congestive heart failure; PVD - peripheral vascular disease; VTE - venous thromboembolism

Note: individuals with CAD, PVD, stroke or VTE at baseline were excluded
chronic hepatitis B were included. Incident myocardial infarction (MI) rates were calculated and Cox regression used to determine the hazard ratio (HR) for MI by HCV status, adjusting for age and race. C-statistics were used to determine risk discrimination by the FRS, by HCV status and race/ethnicity.

Results: Of 316,514 eligible subjects, 232,816 had calculable FRS: 111,436 HCV-infected and 121,380 uninfected. The table summarizes baseline characteristics and FRS. Age, race/ethnicity, BMI, and baseline FRS (in 10-year CHD risk percent) were similar between HCV-infected and uninfected groups. HCV-infected subjects had higher rates of drug and alcohol abuse and lower LDL-cholesterol. Median (IQR) follow-up was 1437 (758-2059) days in the HCV group and 1547 (824-2159) days in the uninfected. Incident MI rate in the HCV and uninfected groups was 7.11 and 7.70 per 1,000 person years, respectively. Adjusted for age and race, the HR for incident MI in HCV vs uninfected persons was 0.92 (95% CI 0.87-0.96, p<0.001). C-statistics were 0.62 (HCV) and 0.61 (uninfected), and by racial/ethnic group, 0.61 (White), 0.61 (Black), and 0.62 (Hispanic).

Conclusions: There was no difference in FRS performance by HCV status. The FRS performed similarly poorly across HCV status and racial/ethnic groups in this Veteran Affairs cohort. Because we used incident MI as the CHD outcome measurement and hard CHD includes not only acute MI but also non-MI coronary insufficiency and coronary death, the event rate measured likely underestimates the true CHD event rate and the degree to which FRS under-predicts incident CHD may be even greater. FRS performance in this cohort may be confounded by risk modifying variables and competing risk of non-MI death over the follow-up period.

Table. Baseline characteristics and 10-year Hard CHD Framingham Risk Score (FRS) by HCV status.

HCV Accelerates Non-Liver Mortality in HIV-Infected Patients: A Nationwide Cohort Study

Vincent Mallet1,2, Sophie Thibault2, Yazdan Yazdanpanah4,5, Stanislas Pol1,2, Michael Schwarzinger1,3

Background: HIV worsens the course of HCV infection. Whether HCV infection accelerates HIV progression and non-liver mortality is controversial. HBV treatment guidelines recommend that it be administered to all HIV/HBV patients regardless of liver fibrosis. HCV treatment guidelines recommend that it be administered to HIV/HCV patients with significant (≥F2) liver fibrosis. The aim of this nationwide study was to assess whether HCV hastens overall and non-liver mortality in HIV-infected patients.

Methodology: We conducted a retrospective, longitudinal analysis of the French National Hospital database. All HIV-infected patients receiving hospital care from January 2008 to December 2012 were included, and their medical trajectory was tracked in all French hospitals with use of the International Classification of Diseases (ICD-10), medical procedures, and in-hospital mortality as recorded per stay. Exclusion criteria involved: age below 18 years, non-resident in Metropolitan France; triple infection (HIV/HCV/HBV; HIV/HBV/HDV); autoimmune, genetic, biliary and vascular liver diseases; and patients identified at cohort inception with AIDS-defining conditions, liver-related events (end-stage liver disease, hepatocellular carcinoma, liver transplant),...
hemophilia, dialysis, organ transplant, and a Charlson Comorbidity Index > 0. A Cox model was initially used to estimate the overall risk of death adjusted for gender, age, and alcoholism; time-dependent covariates were then incorporated to control for the competitive risks of liver-related events or AIDS-defining conditions.

**Results:** Of 70,559 HIV-infected patients (male 65.2%; mean age 42.8 years), 2,385 deaths occurred in 248,885 patient-years. Overall mortality was higher in 8,374 (7.5%) HIV/HCV patients as compared to 60,016 (2.8%) HIV patients (HR 1.79, P < 0.0001), while it did not differ in 1,669 (3.9%) HIV/HBV patients (HR 1.22, P = 0.08). When competitive risks were taken into account, non-liver-related mortality as well as non-liver, non-AIDS-related mortality remained higher in HIV/HCV coinfected patients (HR 1.40, P < 0.0001 and HR 1.47, P < 0.0001, respectively).

**Conclusions:** HCV infection increases overall and non-liver-related mortality in HIV-infected patients. This was not found in HIV/HBV infected patients, suggesting that viral suppression should be recommended for HCV coinfection as it is for HBV coinfection.

**691 The Role of HBV Quasispecies Diversity & Other Factors in Residual HBV Viremia On TDF-Based cART**

Jennifer Audsley1, 2, Anchalee Avihingsanon3, Gail Matthews3, Margaret Littlejohn4, Stephen Bent3, Lilly Yuen5, Fabio Luciani6, Stephen Locarnini7, Sharon Lewin8, 9, Joe Sasadonux1, 2
1Infectious Diseases, Monash University, Prahran, Australia, 2Infectious Diseases, Alfred Hospital, Prahran, Australia, 3Infectious Diseases, HIV-NAT Research Collaboration, Bangkok, Thailand, 4Kirby Institute, Sydney, Australia, 5Victorian Infectious Diseases Reference Laboratory, North Melbourne, Australia, 6Molecular and Biomedical Science, Adelaide University, Adelaide, Australia, 9University of New South Wales, Sydney, Australia

**Background:** Tenofovir (TDF) is effective in suppressing HIV and HBV replication in HIV-HBV co-infection. HBV DNA can persist in some individuals on TDF-based combination antiretroviral therapy (cART) but HBV resistance to TDF has not been reported to date. We initiated this study to determine risk factors associated with detectable HBV DNA beyond 6 months on TDF and to examine HBV polymerase in HIV-HBV co-infected individuals receiving TDF.

**Methodology:** We enrolled 92 HIV-HBV co-infected participants on, or about to commence, TDF-containing ART in a prospective longitudinal study. Subjects were followed every 6 months for 2 years with clinical and laboratory assessments. HBV polymerase sequencing was performed on plasma samples with an HBV DNA > 400 IU/ml by both population-based methods and ultra-deep pyrosequencing (UDPS). Quasispecies diversity was assessed using Shannon entropy (SE) values from 55 pre-TDF samples that underwent UDPS.

**Results:** Most of the cohort (92.4%) was on TDF at study entry (median duration on TDF of 2.03 (IQR 1.0–4.4) years). Over 24 months of follow-up, HBV DNA was > 15 IU/ml once in 10.9% (n = 10); and on > 1 occasion in 7.6% (n = 7); median number of occasions = 3 (IQR 2–5). Eight patients with detectable HBV DNA once during follow-up had HBV DNA < 15 IU/ml at enrolment. Three patients (3.3%) had persistently detectable HBV DNA during follow-up despite adherence to ART. Detectable HBV DNA at study entry, positive HBeAg, country of recruitment, HBV genotype, lower platelets, urea, phosphate and albumin, and higher GGT were associated at the univariate level with detectable HBV DNA on TDF. HBV DNA at study entry was the only factor that remained significant in a series of multivariate models. Novel HBV pol mutations were not identified in any on-TDF plasma samples that underwent HBV sequencing (n = 19). There was no statistical difference in median SE values between the always HBV aviremic on-TDF (n = 41) and the ever viremic on-TDF (n = 14) groups, at both site-by-site and haplotype levels.

**Conclusions:** Detection of HBV DNA on more than one occasion in HIV-HBV co-infected patients on TDF containing cART is common, however, drug resistance did not occur in this setting. HBV DNA positive status at study entry but not preTDF HBV quasispecies diversity was associated with detectable HBV DNA on-TDF. Prolonged follow up will be needed to determine the clinical significance of detectable HBV DNA on HBV-active ART.

**692 Therapeutic Management and Evolution of Chronic Hepatitis B: Does HIV Coinfection Still Matter?**

**Background:** The EPIB 2012 study was conducted to compare the management of chronic hepatitis B (CHB) in HIV-positive and HIV-negative patients, its evolution over time and the relationship with the current presentation of CHB.

**Methodology:** 755 consecutive patients with past or present CHB were seen in October 2012 in 19 French participating centers. All of their data were retrospectively collected from the first visit onwards through a standardized questionnaire. Out of these, 709 with known HIV status and with at least two HBV serological evaluations were analyzed.

**Results:** The 299 HIV-positive patients were less likely to have full initial evaluation of CHB (9.7% vs. 42.9%, p < 10−3), were followed for a longer duration (11.3+/−8.8 vs. 8.6+/−6.9 years, p < 10−3) and more frequently treated for HBV (95.3% vs. 56.8%, p < 10−3) than the 410 HBV-mono infected ones. Undetectable HBV at the last visit (80.8% in HIV-positive vs. 55.1% in HIV-negative patients, p < 10−3) was positively associated in multivariate analysis with
older age (OR + 1 year 1.03, 95% CI 1.01-1.05, p<0.02), lower baseline HBV DNA (OR + 1 log IU/mL 0.87, 95% CI 0.80-0.95, p=0.001), longer duration of HBV therapy (OR + 1 month 1.02-1.03, p<0.01), and negatively with previous lamivudine monotherapy (OR 0.31, 95% CI 0.15-0.66, p=0.002), but not with HIV status. Similar efficacy was observed for tenofovir and entecavir, whatever the HIV serostatus. Renal impairment (creatinine clearance<60 ml/min) was associated with older age and low baseline creatinine clearance, but not with HIV status. Cirrhosis was associated with age (OR + 1 year 1.06, 95% CI 1.04-1.09, p<0.01), male gender (OR 1.78, 95% CI: 0.93-3.41, p=0.08), daily alcohol intake>40g (OR 1.78, 95% CI: 1.14-2.78, p=0.01), and co-infection with HCV (OR 2.61, 95% CI: 1.11-6.26, p=0.03), HDV (OR 2.61, 95% CI: 1.07-6.36, p=0.03), but not with HIV. Hepatocellular carcinoma (HCC) was less frequent in HIV-positive patients (2/297, 0.7% vs 19/410, 4.7%, p=0.002), and was associated with older age (OR + 1 year 1.05, 95% CI 1.01-1.09, p=0.01), male gender (OR 10.00, 95% CI: 1.27-78.60, p=0.03), and cirrhosis (OR 10.11, 95% CI: 3.43 - 29.82, p<0.01), and negatively with HIV-positive status (OR 0.15, 95% CI 0.03-0.67, p=0.01).

Conclusions: Even though the assessment of CHB still has to be improved, the negative impact of HIV on CHB seems to be disappearing probably due to the immunovirological impact of HAART and the more frequent and longer use of HBV therapy. The unexpected lower rate of HCC in HIV-positive patients suggests that a higher rate of viral suppression on long-term HBV therapy could reduce the risk. In light of these results, the management of chronic hepatitis B in HBV mono-infected patients and that in HIV-HBV co-infected patients could become closer in the near future.

693 Increased Hepatitis B Virus Coinfection Screening Following a Change in Zambian HIV Guidelines

1Centre for Infectious Disease Research in Zambia, Lusaka, Zambia, 2Institute of Global Health and Infectious Diseases, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 3University Teaching Hospital, Lusaka, Zambia, 4Obstetrics and Gynecology, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 5Institute for Infectious Diseases, University of Bern, Bern, Switzerland, 6Institute of Social and Preventive Medicine, University of Bern, Bern, Switzerland

Background: Screening all HIV-infected adults for hepatitis B virus (HBV) co-infection is recommended by the World Health Organization but is not commonly practiced in sub-Saharan Africa. In 2010, the Zambian Ministry of Health (MoH) recommended a change from targeted screening, based on clinical suspicion of liver disease, to universal HBV screening at enrollment. We describe changes in HBV screening practices in the Lusaka public-sector HIV treatment and care program following dissemination of the new guidelines in 2011.

Methodology: Using central laboratory testing data from Lusaka public-sector HIV care facilities, across quarters of calendar time, we analyzed the proportion of HIV-infected patients who were screened for HBV co-infection with hepatitis B surface antigen (HBsAg). Using multivariable logistic regression, we assessed predictors of being tested including age, sex, liver transaminases (AST and ALT), and CD4+ T-cell count as well as factors associated with being HBV co-infected.

Results: From 2007 to 2012, 183,413 HIV-infected individuals enrolled across 23 Lusaka clinics. Prior to 2011, 0.9% of enrollees were screened for HBV, of which 170 (14.9%) had positive tests. Having an abnormal ALT was associated with being tested (adjusted odds ratio [AOR] 1.50; 95% confidence interval [CI], 1.26-1.78). Following dissemination of the new guidelines, the proportion of enrollees screened increased rapidly to 29.3% in 2012, and the proportion with positive HBsAg tests decreased to 12.4% (both P<0.001 for trend; Figure 1). Post-guideline change the predictors of being tested included male sex (AOR 1.07; 95% CI, 1.02-1.13), abnormal baseline ALT (AOR 1.12; 95% CI, 1.05-1.20), and baseline CD4+ T-cell count <200 cells/mm3 (AOR 1.25; 95% CI, 1.19-1.32). Testing patterns also varied across facilities due to a lag in the roll out of the guidelines and due to constrained resources. Among those screened, age <40 years (AOR 1.21), male sex (AOR 1.61), abnormal baseline ALT (AOR 2.20), and enrollment CD4+ T-cell count <200 cells/mm3 (AOR 1.61) were associated with HBV co-infection (all P<0.05).

Conclusions: Implementation of new Zambian HIV guidelines was associated with a large increase in HBV screening; however, overall screening rates remain low. In resource-constrained settings, the cost effectiveness of universal HBV screening policies should be determined.

Figure 1. Changes in HBV testing and proportion of HbsAg tests positive in Lusaka public-sector HIV program, 2007-2012
694 HBsAg Genetic Elements Critical for Immune Escape Drive HBV Reactivation Upon Immunosuppression

Background: HBV reactivation is defined as an abrupt reappearance or rise of serum HBV DNA in patients (pts) with resolved or inactive HBV infection. The role of HBsAg genetic diversity in this phenomenon is still anecdotic. Here, we investigate HBsAg genetic signatures underlying HBV reactivation under immunosuppression.

Methodology: This study included 129 HBV D Genotype HBsAg sequences from 29 pts with HBV reactivation triggered by immunosuppressive therapy (55.2% received rituximab, 20.7% other immunosuppressive chemotherapeutics and 24.1% corticosteroids), and 100 chronically HBV infected drug-naive pts as control. For 21/29 HBV-reactivating pts, HBsAg ultra-deep sequencing (UDPS) was also performed. After applying a correction pipeline and error rate estimation using an HBV plasmid, mutations in both forward and reverse primers in >5 reads were considered. Association of mutations with HBV reactivation was assessed by Fisher test with Benjamini-Hochberg correction for multiple comparison.

Results: At HBV reactivation, median serum HBV DNA is 6.1 (4.6-7.9) IU/ml and median ALT is 193 (37-560) IU/L. Among 9 HBV reactivating pts despite lamivudine prophylaxis, lamivudine resistance is detected in 7 pts. A significantly higher mean HBsAg genetic divergence is observed in HBV-reactivating pts than controls (0.058 vs 0.017, P<0.001). Independently from drug resistance presence, specific HBsAg mutations tightly correlate with HBV reactivation (M103I, T123N, S143L, D144E, S154L, Y190A) (P from 0.039 to 0.002). At least 1 of them occurs in 55.2% HBV reactivating pts, while they are absent (0/100 for M103I, T123N, D144E, S154L), or nearly absent (1/100 for S143L and 2/100 for Y190A) in controls. By UDPS, the intra-patient prevalence of these HBsAg mutations ranges from 81.6% to 100%, supporting their full fixation in viral population.

M103I, T123N, S143L, D144E reside in the a-determinant and are known to hamper HBsAg recognition by neutralizing antibodies. Among them, T123N introduces an N-linked glycosylation-site, potentially reducing HBsAg immunogenic surface. S154L and Y190A reside in CTL epitopes encompassing residues150-158 and 185-194.

UDPS also detects minority HBsAg immune/vaccine escape mutations (G145R, G130R, P120S and M133T) and HBsAg stop codons (known to increase HBV oncogenic potential) in 33.3% and 23.8% pts with an intra-patient prevalence ranging from 1.7% to 3.7% and from 1.5% to 2.2%, respectively.

Conclusions: HBV reactivation status is driven by a complex quasispecies with enhanced capability to evade immune response. This highlights the need of a careful monitoring and of establishing an adequate (high genetic barrier?) therapy in order to prevent HBV reactivation and consequent liver damage.

695 Isolated Hepatitis B Core Antibody Is Associated With Advanced Hepatic Fibrosis
Debika Bhattacharya1, Chi-hong Teeng1, Jan Tate2, 5, Vincent Lo Re6, 7, Cynthia Gibert8, 7, Joseph K. Lim2, 3, Maria Rodriguez-Barradas1, 9, David Rimland10, 11, Amy C. Justico1, 12, Matthew B. Goetz13, 11
1David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, United States, 2VA Connecticut Healthcare System, West Haven, CT, United States, 3Yale University School of Medicine, New Haven, CT, United States, 4VA Medical Center, Philadelphia, PA, United States, 5Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States, 6Washington DC VA Medical Center, Washington, DC, United States, 7Philadelphia VA Medical Center, Philadelphia, PA, United States, 8Emory University School of Medicine, Atlanta, GA, United States, 9VA Greater Los Angeles Healthcare System, Los Angeles, CA, United States, 10David Geffen School of Medicine at UCLA, Los Angeles, CA, United States

Background: The relationship between isolated hepatitis B virus (HBV) core antibody (sole HBcAb) and liver disease in HIV+ patients is unclear. We determined if sole HBcAb was associated with advanced hepatic fibrosis in HIV+ persons.

Methodology: We conducted a cross-sectional study among HIV+ patients in the Veterans Aging Cohort Study Virtual Cohort who had available laboratory data to determine chronic HCV status and 5 serological patterns of HBV antibodies: 1) sole HBcAb, 2) resolved HBV infection (HBcAb+/HBsAb+), 3) no other HBV serological pattern, regardless of HCV status.

Results: Among 18,145 HIV+ patients (6,798 with and 11,347 without chronic HCV), sole HBcAb was more common in patients with chronic HCV than without (40% vs 13%; p<0.001). As shown in the table, compared with patients who were non-immune, HIV+ patients with sole HBcAb had a higher OR for advanced hepatic fibrosis by FIB-4 (OR 1.32, 1.09-1.58 and 1.65, 1.20-2.28, respectively) and APRI (OR 1.40, 1.15-1.71 and 1.88, 1.25-2.84, respectively). No association between sole HBcAb status and advanced hepatic fibrosis was seen among HCV- patients. Patients with active HBV had a higher prevalence of advanced hepatic fibrosis than did patients with any other HBV serological pattern, regardless of HCV status.

Conclusions: HIV+ persons with sole HBcAb have evidence of a higher prevalence of advanced hepatic fibrosis, as assessed by FIB-4 or APRI scores, than persons who are non-immune to HBV, who have resolved HBV, or who are HBsAb+ only. These findings suggest that persons with sole HBcAb may be at increased risk of clinical liver complications, and are consistent with prior studies showing an increased prevalence of occult HBV infection in such individuals.
696 Isolated Hepatitis B Core Antibody and Hepatic Fibrosis in HIV/HCV-Coinfected Women

Audrey L. French1,2, Ann Ponton3, Mary Young4, Marek Nowicki5, Michael Augenbraun6, Kathryn Anastos7, Marion Peters8

1Division of Infectious Diseases, Ruth M Rothstein CORE Center, Chicago, IL, United States, 2Stroger Hospital of Cook County, Chicago, IL, United States, 3Ruth M Rothstein CORE Center, Chicago, IL, United States, 4Georgetown University Medical Center, Washington, DC, United States, 5University of Southern California Keck School of Medicine, Los Angeles, CA, United States, 6Division of Infectious Diseases, State University of New York Downstate Medical Center, Brooklyn, NY, United States, 7Montefiore Medical Center, Bronx, NY, United States, 8University of California San Francisco, San Francisco, CA, United States

Background: Isolated hepatitis B (HB) core antibody positivity (anti-HBc) is a common serologic finding in HIV and HCV infected persons. The clinical significance of isolated anti-HBc is uncertain; it may represent resolved HB infection with low anti-HBs, a false positive, the window period in acute HB or, as some have postulated, clinically significant occult active HB infection. We sought to determine if the trajectory of liver disease progression (LDP) in HIV/HCV co-infection is affected by isolated anti-HBc status.

Methodology: We performed a nested study of HIV/HCV-infected women participating in the Women’s Interagency HIV Study (WIHS), a longitudinal observational study. HCV is defined by HCV RNA positivity. We performed enhanced liver fibrosis (ELF) markers on HIV/HCV infected women, comparing women with isolated anti-HBc to women with either negative HB serologies, anti-HBs alone, or both anti-HBs and anti-HBc. ELF, a serum marker that combines direct measures of extracellular matrix remodeling and fibrosis (tissue inhibitor of metalloproteinase-1, hyaluronic acid and propeptide type III collagen), was performed on stored serum q2 years for women with no or minimal fibrosis by APRI and FIB-4 at the baseline visit. We included women who had at least 3 ELF determinations and compared LDP in women with and without isolated anti-HBc using mixed effects linear regression models.

Results: 361 HIV/HCV infected women were studied, including 138 with isolated anti-HBc and 223 without. A median of 6 (IQR 5-7) biannual ELF values were available. At first ELF measurement, median age was 40, 62% of women were black, 21% Latina, 15% white, median CD4 count (CD4) was 359; there was no difference between the groups in terms of race, age, CD4, HIV RNA, HAART use or alcohol use. ELF increased over time from a median of 9.07 for women with isolated anti-HBc and 9.10 for those without to 9.81 and 9.78 respectively (Figure) with no difference in degree of change (p=0.170) by isolated anti-HBc status in the mixed effect model including age, race, history of injection drug use at the index visit, CD4, HAART use, and alcohol use. Factors independently associated with LDP were older age, lower CD4 and HAART non-use.

Conclusions: Isolated anti-HBc was not associated with accelerated liver disease progression over a median of 10 years among HIV/HCV co-infected women.
Effectiveness of Taiwan Nationwide HBV Vaccination in Persons at Risk for HIV Infection
Hsin-Yun Sun1, Chia-Jui Yang2, Nan-Yao Lee3, Shiou-Haur Liang4, Chien-Ching Hung1
1National Taiwan University Hospital, Taipei, Taiwan, 2Far Eastern Memorial Hospital, New Taipei City, Taiwan, 3National Cheng Kung University Hospital, Tainan, Taiwan, 4E-Da Hospital, Kaohsiung, Taiwan

Background: The prevalence of chronic hepatitis B virus (HBV) infection was estimated 15% to 20% in the adults, regardless of HIV infection, who were born before universal neonatal hepatitis B virus (HBV) vaccination program was launched in 1986. The neonatal HBV vaccination program and catch-up vaccination program have significantly reduced acute and chronic HBV infection among persons born in the universal HBV vaccination era. However, the long-term effectiveness of the programs remains rarely investigated among the adults who were born in the universal vaccination era and engaged in high-risk sexual behavior.

Methodology: Between April 2006 and December 2012, we determined HBV serological markers (HBsAg, anti-HBs, and anti-HBc), anti-HCV, and rapid plasma regain (RPR) titers among HIV-infected men who have sex with men (MSM) born during 1984-1985 (Group I) and those born in or after 1986 (Group II), and HIV-uninfected MSM (Group III) and heterosexuals (Group IV), both of whom were born in or after 1986 and sought anonymous voluntary counseling and testing for HIV infection. Prevalence of HBsAg positivity and incidence of HBV infection were estimated and multivariate analysis was performed to identify factors associated with HBsAg positivity.

Results: During the study period, 244 persons in Group I, 523 in Group II, 377 in Group III, and 217 in Group IV were included. Group I had a significantly higher prevalence of HBsAg (7.8%), anti-HBc (30.3%), anti-HCV (4.3%), and syphilis (RPR titers ≥4) (19.8%) than the other three groups (HBsAg: 3.7%/2.4%/3.2%; anti-HBc: 26.3%/19.6%/18.0%; anti-HCV: 3.5%/1.1%/1.4%; and syphilis: 21.2%/2.6%/0.5% for Groups II/III/IV, respectively). After adjustments for HIV seropositivity, birth year syphilis, and anti-HCV seropositivity in multivariable analysis, HBsAg seropositivity was significantly associated with syphilis (OR 2.990; 95% CI 1.502-5.953) and anti-HCV seropositivity (OR 3.402; 95% CI 1.091-10.614), but not birth year in or after 1986 (OR 0.421; 95% CI 0.208-0.854) (All P<0.05). In Group II with all negative HBV markers at baseline, the incidence rate of HBsAg seroconversion was 0.486 episodes per 100 person-years; and for those who received combination antiretroviral therapy containing tenofovir and/or lamivudine, none developed HBsAg seroconversion.

Conclusions: For the adults born after 1986 and engaged in high-risk sexual behaviors, universal neonatal HBV vaccination and catch-up vaccination programs offered long-term protection against HBsAg seropositivity and HBsAg seropositivity was associated with syphilis and anti-HCV seropositivity.

Hepatitis B Virus Mother-To-Child-Transmission Among HIV-Infected Pregnant Women in Kenya
Timothy D. Minniear1, 2, Alex Morwabe3, Sonali Girde1, 4, Fredrick Harrison2, Frank Angira3, Boaz Gyoar, Lisa A. Mills1, 3, Clement Zeh1, 3, Philip J. Peters1
1CDC, Atlanta, GA, United States, 2St. Jude Children’s Research Hospital, Memphis, TN, United States, 3KEMRI/CDC Research and Public Health Collaboration, Kisumu, Kenya, 4ICF International, Atlanta, GA, United States, 5KEMRI/CDC Research and Public Health Collaboration, Kisumu, Kenya

Background: Like HIV, hepatitis B virus (HBV) can be transmitted from mother to child. Our objective was to assess the prevalence of HBV co-infection and the HBV vertical transmission rate among HIV-infected mothers receiving lamivudine-containing triple-antiretroviral (ARV) regimens.

Methodology: The Kisumu Breastfeeding Study (2003-2009) was a prospective clinical trial of triple-ARV regimens to prevent mother to child HIV transmission (MTCT) in Kenyan women. Women received ARV regimens containing lamivudine from 34 weeks’ gestation through six months of postpartum breastfeeding. Infant HBV vaccination starts at six weeks of life in Kenya. We retrospectively performed maternal HBV serology testing, including surface antigen (HBsAg), surface antibody (HBsAb), core antibody (HBcAb), and e antigen (HBeAg), in serum at enrollment (pre-ARV) and at six months postpartum. Maternal active HBV co-infection was defined as having detectable HBsAg. We tested infants of mothers with detectable HBsAg or an isolated HBcAb (HBsAb/-/HBcAb+/HBSAb-) for HBcAb at two years of life. Infant HBV infection was defined as having detectable HBcAb.

Results: Among 439 HIV-infected women initiating lamivudine-containing ARVs, 25 (5.7%) had active HBV co-infection, including 9 (38%) women with detectable HBeAg. Among infants with available specimens, there were 0/17 HBV MTCT in infants of mothers with HBsAg+.
active HBV (0%, 95% confidence interval [CI] = 0%-16%) and 0/46 HBV MTCT in infants of mothers with isolated HBcAb (0%, 95% CI = 0%-6%). HBV co-infected mothers did not significantly differ in CD4 count, alanine aminotransferase (ALT) levels, or rates of liver toxicity on ARVs compared with those without HBV co-infection (Table).

Conclusions: The prevalence of active HBV co-infection in this cohort of HIV-infected pregnant women (5.7%) was almost double the reported Kenyan prevalence (3%). Among HIV/HBV co-infected women receiving lamivudine containing triple-ARV regimens, there were no cases of HBV MTCT suggesting that vertical transmission of HBV is uncommon in this setting.

699 Vaccine Escape Mutants and Suboptimal Hepatitis B Virus Response in HIV HBV Coinfected Patients
Anders Boyd1, Raoul Moh2, Paul Dény3, Mariama Issoufou4, Christine Danel5, Xavier Anglaret6, Serge Ethéol7, Pierre-Marie Girard1, Fabien Zoulim3, Karine Lacombe4
1Inserm UMR-S907, Paris, France; 2Programme PACC, Abidjan, Côte d'Ivoire; 3Centre de Recherche sur le Cancer de Lyon, Equipes 15 et 16, INSERM, Unité 1052, CNRS, UMR 5286, Lyon, France; 4Department of Infectious and Tropical Diseases, Saint-Antoine Hospital, Paris, France

Background: Immune and antiviral-associated S gene mutations are associated with potent vaccine escape virus and are thus a major public health concern. The frequency of these mutations during antiretroviral therapy (ART) is unknown in ART-naive HIV hepatitis B virus (HBV) coinfected patients with suboptimal HBV response, especially in sub Saharan Africa.

Methodology: 200 ART naïve, HIV-infected patients with positive hepatitis B surface antigen were selected from two randomized-control trials in Côte d’Ivoire: ANRS 1269, comparing treatment interruption strategies of lamivudine (LAM)-containing ART (n=103), and ANRS 12136, comparing early or delayed initiation of tenofovir (TDF)/emtricitabine-containing ART (n=97). HBV DNA was quantified using an in-house assay (detection limit: <12 copies/mL) while preS/S regions of positive samples were sequenced. Patients with detectable HBV DNA at baseline were included in this analysis (LAM n=88, TDF n=51). Determinants for time to undetectable HBV DNA viral load were modeled using Cox proportional hazards model.

Results: Patients were mostly female (68%) with median 35 years of age (IQR: 30-40). At baseline, 39 (28.1%) patients were HBeAg positive and 37 (31.4%) had an ALT of >35 IU/mL. Patients harbored A (n=2) or E (n=97) HBV genotype. After a median 35.5 (IQR: 24.3-36.5) months of follow-up, higher rates of undetectable HBV DNA were observed in TDF vs LAM-treated patients (cumulative % at M36, 94.4% vs 76.1% respectively, HR=1.64, 95%CI: 1.01-2.66, p=0.046) and in patients with lower degrees of immunosuppression [compared to >500 CD4+ cells/mm3, HR (95%CI) at 350-500/mm3=1.07 (0.67-1.71); at 250-350/mm3=0.62 (0.34-1.11); at <250/mm3=0.41 (0.19-0.90)] after adjusting for baseline HBV DNA level, HBeAg status and percent of on-treatment follow-up time. In patients with available sequences at baseline (N=49), amino acid changes at positions recognized as immune and antiviral-associated S gene mutations were as follows: sP120A/L/T (n=3), sE164G/V (n=6) and s194 (n=0). Among patients with low detectable HBV DNA levels at the end of follow-up (<105 log10 copies/mL, LAM n=25, TDF n=5), incident amino acid changes were noted at positions: sI110L, sI126I, sA128D, sG130K, sM133L, sI213L, sF219G, and s220C, but not at s120, s145, s164, or s195. Among patients with HBV DNA ≥105 log10 copies/mL at the end of follow-up (LAM n=8, TDF n=3), the only incident S gene mutations observed during follow-up were at both positions sI164D+sI195M in two LAM-treated patients (while also harboring rtV173L+rTL180M+rTM204V/i mutations) but not in any TDF-treated patient.

Conclusions: In HIV-HBV coinfectected patients with low transaminases levels, immune and antiviral-associated S gene mutations are rare during suboptimal response.

700 Long-Term Benefit of Tenofovir On Hepatitis Delta
Rocio Sierra-Enguita, Zulema Plaza, Eugenia Vispo, Pablo Barreiro, Pablo Labarga, José Vicente Fernández-Montero, Carmen De Mendoza, Vicente Soriano
Infectious Diseases, Hospital Carlos III, Madrid, Spain

Background: Hepatitis delta virus (HDV) infection produces the most severe form of chronic viral hepatitis. Treatment with peginterferon gives only limited benefit on delta hepatitis. Since HDV replication requires HBsAg and tenofovir is amongst the most potent anti-HBV agents and is widely used as part of HIV therapy, we explored whether prolonged tenofovir (TDF) exposure might be of benefit on hepatitis delta.

Methodology: All HIV-infected patients with hepatitis delta treated with TDF followed at an HIV clinic in Spain were retrospectively identified. Serum HBV/HDV-RNA was quantified using a commercial real-time PCR assay. Liver fibrosis was measured using elastometry (FibroScan). Significant liver fibrosis regression (sLFR) was defined as a 30% reduction in hepatic stiffness compared to baseline.

Results: A total of 19 HIV-infected patients with hepatitis delta were identified. HCV antibodies were present in 16 (84%), although HCV-RNA was detectable only in 3 (2%). Overall 79% were former intravenous drug users; 95% male; median age 48 years-old. HDV genotype 1 was present in all cases. HBV genotypes D and A were the most common (53% and 26%, respectively). Prior lamivudine exposure (median 59 months) before beginning TDF was recognized in 9 (47%), being the rest naïve for any anti-HBV agent.

After a median TDF exposure of 58 [34-93] months, all achieved undetectable HBV-DNA and 10 (53%) reached HDV-RNA <10 copies/mL. In the last group, the median time for the achievement of undetectable HDV-RNA was 54 [33-72] months. Of note, in the subset of HDV viremic patients at the end of follow-up there was also a median drop in HDV-RNA of 2.42 [1.27 - 3.09] log cop/mL. sLFR was recognized in 6 (60%) out of 10 patients who achieved undetectable HDV-RNA and in none of 9 that remained viremic at the end of follow-up (p=0.02). Median liver enzymes slightly declined during the study period, but normalized in only 3. There were no significant changes in serum HBsAg levels during the study period, although HBsAg seroclearance occurred in 2 patients, who became negative for serum HDV-RNA.

Conclusions: Long-term exposure to TDF significantly reduces serum HDV-RNA besides completely suppress HBV-DNA in HIV-infected patients with hepatitis delta. This effect is accompanied by significant liver fibrosis regression.
Background: Background & Aims: The seroprevalence of the Hepatitis E virus (HEV) and its chronicity rate in the HIV-infected population has not been well established. Consequently, the magnitude of this emerging disease in this population cannot be established. The objective of our study was to evaluate the serological/virological HEV situation and factors associated with it in HIV-infected patients.

Methodology: Prospective study in Southern Spain that included HIV-infected patients who were followed up between September 2012 and May 2013. All patients included were tested for anti-HEV IgG/IgM. In those patients with confirmed anti-HEV IgG/IgM positivity, a RT-PCR was performed. In patients where HEV-RNA was amplified, a second RT-PCR was performed 6 months later to identify transient or chronic HEV infections. Additionally, we performed a RT-PCR in all patients with CD4+ cell counts that were lower than 200 cells/mL regardless of the anti-HEV IgG/IgM status. HEV seroprevalence and its associated factors were evaluated.

Results: Eight-hundred and ninety-four HIV infected patients were enrolled in the study. Of these patients, 399 (44.6%) were monoinfected with HIV; 462 (51.6%) were co-infected with HIV/HCV; 12 (1.3%) were co-infected with HIV/HBV; and 21 (2.3%) were co-infected with HIV/HCV/HBV. In 88 patients, anti-HEV IgG/IgM (86 IgG+/-/IgM- and 2 IgG+/IgM+) were detected, and consequently, the overall HEV seroprevalence in our population was 9.8% (95% CI: 8.02%-11.9%).

Conclusions: Our study found that despite HEV infection is frequent in HIV-infected patients, the detection of HEV-RNA in our study was low, and no development of chronic infection was found. Furthermore, in immunosuppressed patients with the absence of HEV-serum-marker positivity, HEV-RNA was not detected.
701  Monoclonal Gammopathy and HIV-1 Infection: Evolution With Highly Active Antiretroviral Therapy
Marie-Laure Casanova, Alain Makinson
1Infectious Diseases, CHU Gui de Chauliac, Montpellier, France, 2Infectious Diseases, University Hospital Montpellier, Montpellier, France

Background: Monoclonal gammopathies (MG) associated with HIV infection are frequent but their significance and evolution are uncertain in this population with a high risk of lymphoproliferative disorder. Our aim was to describe the evolution of MG in HIV-infected subjects under highly active antiretroviral therapy (HAART).

Methodology: Retrospective study of HIV-1 infected adults, with a monoclonal spike identified by the serum protein electrophoresis confirmed by immunofixation, excluding subjects with concomitant or preceding hemopathy. Subjects were followed for at least 3 years if MG persisted or less if MG disappeared. Logistic regression models were used to identify factors associated with disappearance of monoclonal band.

Results: Seventy-one subjects were included: 65% were male, median age was 41 years, 46% had AIDS, median nadir CD4 count was 237/mm3, 41% had chronic hepatitis B or C infection. Eighteen subjects with preceding or concomitant hemopathy were excluded. After a median follow-up of 7.1 years (IQR 4.5-9.3), 71.8% showed spike disappearance. In multivariate analysis, MG disappearance was associated with HIV-virologic success (OR 6.67, CI95% [1.38;32.13], p 0.018), absence of active hepatitis C at end of follow-up (OR 11.16, CI95% [2.20;56.69], p 0.004) and age inferior to 40 years (OR 4.75, CI95% [1.00;22.55], p 0.050). One subject developed a myeloma after the diagnosis of an IgA kappa MG.

Conclusions: MG associated with HIV infection concerned a young population, and had a favorable evolution on HAART in most cases. The disappearance of monoclonal gammopathy was associated with HIV-virologic success, absence of active hepatitis C and younger age.

702  Predicting Survival of HIV-Infected Patients With Liver Cancer: The SHILCA Score and Staging Model
Nicolas Merchante, Ting-Yi Chen, Eugenia Vispo, Mamta Jain, Emma Page, Pablo Barreiro, Mark Nelson, Judith Aberg, Juan A. Pineda, Jorge Marrero, Norbert Bräu
1Hospital Universitario de Valme, Sevilla, Spain, 2University of Texas Southwestern Medical Center, Dallas, TX, United States, 3Hospital Carlos III, Madrid, Spain, 4Chelsea and Westminster Hospital & Imperial College, London, United Kingdom, 5Bellevue Hospital Center & New York University School of Medicine, New York, NY, United States, 6Infectious Disease Section, James J. Peters VA Medical Center, Bronx, NY, United States, 7Divisions of Infectious Diseases & Liver Diseases, Icahn School of Medicine at Mount Sinai, New York, NY, United States

Background: Published staging and survival models of hepatocellular carcinoma (HCC), such as Barcelona- Clinic- Liver-Cancer (BCLC), Cancer-of-the-Liver- Italian-Program (CLIP), or Model-to-Estimate-Survival-in-Ambulatory-Patients-with-HCC (MESIAH) have been shown to predict survival in HIV-negative patients. They have not yet been validated in HIV-infected patients with HCC. Furthermore, HIV viral load as well as performance status have both been shown to independently predict survival of HCC in these patients. This study aimed at developing a model to predict survival of HCC in HIV-infected patients that incorporates these two variables.

Methodology: Using Cox proportional hazard analysis in 256 HIV-infected patients with HCC, a multivariable model identified all baseline variables that independently predicted survival: log10 HIV RNA, performance status, age, tumor size, metastases, albumin, and log10 alfa-fetoprotein. The SHILCA score had a median of 2.74 with a range of 0.71 - 5.89. Median survival was 12.0 months overall, and for SHILCA stage A undefined due to <50% deaths; stage B, 27.8 months, stage C, 8.2 months, and stage D, 1.5 months (p=1.33*10 -30 , log rank). Actuarial survival at 1 year was stage A, 92%; stage B, 72%; stage C, 28%; and stage D, 7%. The SHILCA score (Cox chi-square, 137.2; C-statistic, 0.79) predicted survival better than MESIAH (Cox chi-square, 106.7; C-statistic, 0.76), CLIP (Cox chi-square, 92.7; C-statistic, 0.73), and BCLC (Cox chi-square, 43.4; C-statistic, 0.68).

Conclusions: The SHILCA score and staging model that includes HIV viral load, performance status and 5 other baseline variables, can predict survival of HCC in HIV-infected patients with a high degree of accuracy.
Different Immunologic and Virologic Contexts for HIV-Associated Lymphoma in the CNICS Cohort

Satish Gopal1, Monita Patel1, Chad Achenbach2, Elizabeth Yanik1, Stephen Cole1, Sonia Napravnik1, Kristy Richards1, Joseph Eron1, for the CNICS Investigators

1University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 2Northwestern University, Chicago, IL, United States

Background: Pathobiology of HIV-associated lymphoma may be changing in the era of effective antiretroviral therapy (ART). Lymphoma incidence is increased soon after ART, perhaps due to the immune reconstitution inflammatory syndrome (IRIS).

Methodology: In the Centers for AIDS Research Network of Integrated Clinical Systems (CNICS), we characterized patients with Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) between 1996 and 2011 as: (1) on ART ≤6 months with ≥0.5 log10 copies/mL reduction in HIV RNA (unmasking lymphoma IRIS); (2) on ART without IRIS; or (3) off ART. CD4 and HIV RNA during the 12 months before and after lymphoma diagnosis, stratified by IRIS and ART status, were assessed using individual patient-level CD4 and HIV RNA curves. Summative curves were derived by plotting median and interquartile values at each monthly time point across all patients within each group.

Results: Of 24,203 HIV-infected individuals enrolled in CNICS, 482 (2%) were diagnosed with lymphoma between 1996 and 2011. Of these, 56 (12%) had unmasking lymphoma IRIS, 175 (36%) were on ART without IRIS, and 251 (52%) were off ART. Unmasking lymphoma IRIS cases were on ART for 2.2 months (IQR 0.9-3.5), and 48% had HIV RNA <400 copies/mL. On ART cases without IRIS were on ART for 20.3 months (IQR 7.5-42.9), and 58% had HIV RNA <400 copies/mL. Median CD4 and HIV RNA during the 12 months before and after lymphoma diagnosis are shown in Figure 1.

During the 24-month window, there were 3439 CD4 measures for the entire study population [median 8 (IQR 5-10) per patient], and 3266 HIV RNA measures [median 7 (IQR 5-10) per patient]. IRIS cases demonstrated marked reductions in HIV RNA after ART in the months before lymphoma diagnosis, without significant CD4 increases. In the 12 months after lymphoma diagnosis, IRIS cases demonstrated modest CD4 increases. On ART cases without IRIS demonstrated modest CD4 increases and reductions in HIV RNA after lymphoma diagnosis. Off ART cases demonstrated robust CD4 increases and reductions in HIV RNA after lymphoma diagnosis, resulting from ART initiation within six months in 198 of 251 (79%) patients.

Conclusions: In the ART era, HIV-associated lymphoma develops in different immunologic and virologic contexts. The extent to which these differences influence histology, biology, and clinical outcomes remains unclear. Attenuated CD4 increases soon after ART initiation, despite HIV RNA suppression, might suggest developing lymphoma.
Risk of Cancer Among HIV Patients Compared To the Background Population: Impact of Smoking and HIV

Marie Helleberg1, Jan Gerstoft1, Shoab Afzal2, Gitte Kronborg1, Carsten S. Larsen1, Stig E. Bojesen1, Court Pedersen1, Børge G. Nordestgaard2, Niels Obel1
1Department of Infectious Diseases, Copenhagen University Hospital, Rigshospitalet, Copenhagen Ø, Denmark, 2Department of Clinical Biochemistry, Copenhagen University Hospital, Herlev, Herlev, Denmark

Background: The relative impact of immune deficiency and lifestyle related factors on risk of cancer in the HIV infected population is controversial. We aimed to estimate the population attributable fractions (PAFs) of cancer associated with smoking, immune deficiency and with being HIV-infected.

Methodology: In a Danish, nationwide, population-based cohort study, 1995-2011, incidences of cancer were compared between the HIV-infected population and a matched population-based cohort. Analyses were stratified on cancer category (smoking-related, virological or other), smoking status and nadir CD4/duration of CD4<200 cells/μL. We used Poisson regression to estimate incidence rate ratios (IRR). PAFs associated with HIV were calculated by comparing HIV-infected with HIV-uninfected non-smokers.

Results: A total of 3,503 HIV patients and 12,979 population controls were followed for 18,679 and 55,957 person-years. HIV patients were on antiretroviral therapy during 92% of the observation time. Median CD4 at study inclusion was 450 cells/μL (IQR 310-630). Smoking-related and virological cancers accounted for 23% and 43% of cancers in the HIV-infected population (Figure 1). The IRR (95% CI) of smoking-related, virological and other cancers among HIV patients compared to controls were 2.8 (1.6-4.9), 11.5 (6.5-20.5) and 1.0 (0.7-1.3), respectively. Among non-smoking HIV patients compared to non-smoking controls there was increased risk of virological cancer (17.0 (6.0-47.9)), but the risk of non-virological cancers was not elevated (1.2 (0.7-2.1)). The PAFs associated with being HIV infected were 56% for all cancers and 94% for virological cancers. The PAF associated with smoking was 27% for all cancers and 91% for smoking-related cancers. The risk of lung cancer was increased among HIV patients with nadir CD4 <200 cells/μL (IRR (95%CI) 3.54 (1.00-12.59)), but was not associated with duration of CD4 <200 cells/μL (1.07 per year (0.87-1.32)). For non-virological cancers that are not strongly related to smoking the PAF associated with immune deficiency was 0%.

Conclusions: In a well-treated HIV infected population the risk of cancer is increased approximately two-fold compared to the background population. In absence of smoking the increase in risk is confined to virological cancers, whereas the risk of other cancers does not differ between HIV infected and uninfected individuals and does not seem to be associated with immune deficiency.

Cancer Stage at Diagnosis in HIV-Infected Individuals and Transplant Recipients

Meredith S. Shiels1, Glenn Copeland2, Marc Goodman2, Charles F. Lynch3, Karen Pawlish1, Ruth M. Pfeiffer1, Jon J. Snyder4, Eric A. Engels2
1National Cancer Institute, Bethesda, MD, United States, 2Michigan Department of Community Health, Lansing, MI, United States, 3Cedars Sinai Hospital, West Hollywood, CA, United States, 4University of Iowa, Iowa City, IA, United States, 5New Jersey Department of Health, Trenton, NJ, United States, 6Scientific Registry of Transplant Recipients, Minneapolis, MN, United States

Background: Cancer risk is elevated with HIV infection; however, it is unknown whether immune suppression results in more aggressive, advanced stage cancers. As both tumor biology and delayed utilization of health care may lead to late stage of diagnosis among HIV-infected individuals, we compared cancer stage in HIV-infected individuals to solid organ transplant recipients, an immune suppressed population with more frequent utilization of care.
Methodology: We used data on all cases of 15 cancer sites occurring during 1996-2010 in two U.S. registry linkage studies: the HIV/AIDS Cancer Match (HACM) and the Transplant Cancer Match (TCM), which linked cancer registries to HIV and transplant registries, respectively. Cancer registries provided data on Surveillance, Epidemiology and End Results (SEER) summary stage at diagnosis. Odds ratios (ORs) for distant (vs. local) disease were estimated comparing HIV and transplant populations to the general population in separate logistic regression models, adjusted for age, sex, race, registry and calendar year.

Results: In the HACM Study, 9,362 of 4.7 million cancer cases occurred in HIV-infected individuals and in the TCM Study, 8,225 of 9.7 million cancer cases occurred in transplant recipients. Compared to cancer cases in the general population, HIV-infected individuals had more distant stage breast (OR=1.78), lung (OR=1.20), prostate (OR=1.39) and cervical cancers (OR=1.51), and melanoma (OR=2.53), and fewer cases of distant stage anal cancer (OR=0.57) (Figure 1). In contrast, compared to the general population, transplant recipients had fewer distant stage prostate (OR=0.50) and lung (OR=0.59) cancers, and no difference in stage of cervical cancer (OR=0.58) or melanoma (OR=1.33). Similar to HIV-infected individuals, transplant recipients had fewer distant stage anal cancers (OR=0.30).

Conclusions: Prostate, lung, breast, and cervical cancers and melanomas diagnosed in HIV-infected individuals were more likely to be distant stage than in the general population. In contrast among transplant recipients, none of these cancer sites was more likely to be distant stage relative to the general population. This suggests that the increased stage observed in people with HIV is likely driven by delayed diagnosis due to under-utilization of care, particularly for screen-detectable cancers, and is unlikely to be due to immune suppression increasing cancer progression.
**Results:** From 1998 to 2009, a total of 831 male and 127 female HIV/AIDS patients were diagnosed with cancer among 13,804 male and 1,619 female HIV/AIDS patients (59,772 person-years for males and 7,733 person-years for females). Non-Hodgkin lymphoma (n=193; SIR=6.04) was the most common AIDS Defining Cancer (ADC) in males; while cervical cancer was the most common ADC in females (n=49; person-years; SIR=10.15). Kaposi’s sarcoma was also relatively common in male HIV/AIDS patients (n=187; SIR=1921.84). Common sites of Non-ADCs included the oral cavity (SIR=7.44), nasopharynx (SIR=6.52), colon (SIR=6.36), anus or anal canal (SIR=11.18), and liver (SIR=2.91). Survival after cancer diagnosis was longer in women than in men.

**Conclusions:** This is the first population-based cohort study investigating cancer incidence and survival in HIV/AIDS patients in South East Asia. Our study highlights the utility of insurance databases in linkage studies to address epidemiological questions of concurrent co-morbidities. In contrast to reports from other Asian regions, such as India, KS is frequently diagnosed in HIV infected individuals in Taiwan, as well as cancer and NHL the two other ADCs. Our results also identify a spectrum of Non-AIDS defining cancers, including oral, nasopharyngeal, anal, and liver cancer, for which risks are elevated and that are attributable to HIV and other infections.

**707 Excess Burden of Cancer Among HIV-Infected Persons in the United States**

**Hilary A. Robbins**, Meredith S. Shiels, Ruth M. Pfeiffer, Jianmin Li, H. Irene Hall, Eric A. Engels

**Background:** Nearly 1 million people in the U.S. have diagnosed HIV infection and therefore increased cancer risk, but total cancer burden in the U.S. HIV population has not been quantified. We estimated the total number of incident cancers, and the number in excess of expected, among HIV-infected persons in the U.S. during 2010.

**Methodology:** To estimate cancer rates among HIV-infected persons, we applied Poisson models to linked HIV and cancer registry data from 6 states in the HIV/AIDS Cancer Match Study. We used data from the Surveillance, Epidemiology, and End Results (SEER) program for general population (expected) cancer rates. We applied these rates to CDC estimates of people living with diagnosed HIV infection, stratified by age, sex, race/ethnicity, HIV risk group, and AIDS-relative time, to calculate total and excess (i.e., total - expected) cancer cases in 2010.

**Results:** An estimated 7,764 cancers occurred among HIV-infected people, 3,915 (50.4%) in excess of expected. The most common cancer was non-Hodgkin lymphoma (N=1,645, 87.7% excess; Table 1), and nearly all cases were excess for Kaposi sarcoma (N=912, 99.8% excess), anal cancer (N=764, 97.4% excess), and Hodgkin lymphoma (N=317, 90.9% excess). Fewer than expected cases occurred for colorectal cancer (N=357, 5.8% deficit), prostate cancer (N=574, 40.7% deficit), and female breast cancer (N=177, 41.6% deficit). Most cancers occurred among males (N=6,237; 51.5% excess), specifically men who have sex with men (N=4,545; 55.9% excess). By age, the largest excess was among ages 40-49 (N=1,610), though the largest proportional excess was among ages 15-29 (92.7%). There was no excess among the oldest group (age ≥70). While most cancers occurred among non-Hispanic blacks (N=3,293) and whites (N=2,870), a larger proportional excess was among Hispanics (64.4%).

**Conclusions:** HIV infection in the U.S. is associated with a substantial excess burden of cancer, which largely occurs among men and individuals under 50. Despite major improvements in HIV treatment, approximately half of almost 8,000 cancer cases among HIV-infected persons in 2010 were excess cases.

The percentage excess is calculated as excess/total; the percentage deficit is calculated as deficit/expected. Numbers may not sum exactly due to rounding.
The Effect of Protease Inhibitor Use On Kaposi Sarcoma Incidence in a cART-Experienced Cohort

Elizabeth Chiao, Marc Kowalkowski
Baylor College of Medicine, Houston, TX, United States

Background: The incidence of Kaposi Sarcoma (KS) has markedly decreased in countries with widespread availability of combined antiretroviral therapy (cART). Protease inhibitors, and nelfinavir mesylate, in particular, have been shown to confer broad antineoplastic and antiviral activity in in vitro and pre-clinical in vivo studies. It has been hypothesized that protease inhibitors confer a specific reduction in KS risk independent of cART-related immune reconstitution, compared to non-nucleoside reverse transcriptase inhibitors (NNRTI). However, no large confirmatory clinical studies have been conducted.

Methodology: We performed a retrospective cohort study utilizing data from the Veterans Affairs HIV Clinical Case Registry (VA-CCR) from 1985-2010 of all male veterans who had ever received cART. KS cases were identified using ICD-9 codes. We excluded individuals without identifiable CD4 or viral load measurement, and <90 days of follow-up. Prevalent KS cases, defined as those occurring prior to or within 90 days of cART initiation, were excluded. Data for each cART class, defined as: PIs, excluding Nelfinavir (PI), Nelfinavir (NFV), and (NNRTIs) were used to calculate time-updated ratios of the time on each class of cART divided by the total time on cART treatment (“percent of time” on cART). Separate multivariable Poisson regression models adjusted for demographic, immunologic, and time-varying HIV viral load covariates were performed for each cART class “percent of time” variable.

Results: A total of 25,529 HIV+ male Veterans who had ever received cART were identified in the cohort, with 544 incident cases of KS. The overall KS incidence in the cohort was 339.7 (312.4-369.5)/105 person-years (py). The incidence of KS decreased from 458.4 (405.5-518.7)/105 py for those diagnosed in the pre-cART era (pre 1996) to 165.1 (127.4-214.1)/105 py in the late cART era (2002-2010). In multivariable models (table 1), percent of time on PI was associated with a 4% decreased risk of KS per 10% increase in PI use (IRR 0.96, p-value 0.001). However, NFV was associated with a 4% increased risk of KS per 10% increase in NFV use (IRR 1.04, p-value 0.02), and NNRTIs were associated with a small decreased risk of KS, but was not significant (IRR 0.98, p-value 0.11).

Conclusions: In this cohort of HIV+ male Veterans who had ever received cART, PI utilization was associated with a decreased risk of KS. PI utilization may independently decrease KS risk beyond the effects of PIs on immune reconstitution.

| The Effect of cART Drug Class Use on Kaposi Sarcoma Incidence in a cART-Experienced Cohort |
|---------------------------------|----------------|----------------|----------------|

Guidelines On Kaposi’s Sarcoma Treatment: Results From Two Cochrane Systematic Reviews

Esther E. Freeman1, Charles Okwundu2, Oluwatoyin Gbabe3, Miriam Laker4, Philippa Easterbrook5, Toby Maurer6, Jeffrey Martin4

1Department of Dermatology, Harvard Medical School, Massachusetts General Hospital, Boston, MA, United States, 2Centre for Evidence-Based Health Care, Faculty of Medicine and Health Sciences, Stellenbosch University, Tygerberg, South Africa, 3Centre for Evidence-Based Health Care, Faculty of Health Sciences, Stellenbosch University, Tygerberg, South Africa, 4Department of Epidemiology and Biostatistics, University of California at San Francisco, San Francisco, CA, United States, 5HIV Department, World Health Organization, Geneva, Switzerland, 6Department of Dermatology, University of California at San Francisco, San Francisco, CA, United States

Background: Kaposi’s sarcoma (KS) is the most frequently observed HIV-associated malignancy in resource-poor settings. Widespread use of antiretroviral therapy (ART) has reduced KS incidence, but KS incidence remains high in countries where HIV is prevalent, and is still associated with poor survival. The World Health Organization (WHO) does not have guidelines for KS treatment. To that end, we performed two systematic Cochrane reviews of KS treatment in adults, for mild/moderate and severe disease, to aid WHO guideline development.

Methodology: Two systematic Cochrane reviews were undertaken using standard Cochrane HIV/AIDS Review Group search criteria. Randomized controlled trials (RCTs) and observational studies were included, excluding case reports. Adults were divided into two separate reviews a) mild/moderate disease, as defined by ACTG stage T0 disease and b) severe KS, as defined by stage T1 disease. Primary outcomes were mortality and clinical response; secondary outcomes included time to response, KS IRIS, adverse events, and quality of life.

Results: A total of 3,615 relevant abstracts were reviewed. Ultimately, 5 studies (3 RCTs, 2 cohorts) were included in treatment for mild/moderate KS, and 9 studies (6 RCTs, 3 cohorts) were included for severe KS. For adults with mild/moderate KS, there was no survival advantage to using a PI-based ART regimen as compared to a non-PI based regimen. Comparing chemotherapy plus ART to ART alone for mild/moderate KS, there were no studies designed
or powered to address outcomes. The 2 RCTs and 2 cohorts that included a small number of patients with mild/moderate disease found no difference in survival or treatment response comparing ART plus any type of chemotherapy to ART alone. For adults with severe KS, comparing ABV (bleomycin, vincristine, doxorubicin) plus ART to ART alone, no mortality benefit was observed, but overall clinical response (risk ratio 1.78; 95% CI 1.16 to 2.72) and reduced disease progression (RR 0.1; 95% CI 0.01 to 0.75) favored ABV plus ART. Comparing liposomal anthracyclines plus ART to ART alone, clinical response favored liposomal anthracyclines but was not statistically significant (of note two large RCTs had to be excluded due to a mixture of KS stages).

Conclusions: For adults with severe KS, chemotherapy in addition to ART as compared to ART alone provides a clinical response benefit and prevents progression of disease. For adults with mild/moderate KS, since no study was designed or powered to address this question, we are lacking definitive evidence of whether there is a survival or clinical response advantage of adding chemotherapy to ART. These Cochrane reviews will inform guidelines on KS treatment, through forthcoming WHO Guidelines on Skin and Oral Conditions in HIV positive Adults and Children.

710 Randomized Trial of Protease Inhibitor-Based Antiretroviral Therapy for Kaposi Sarcoma in Africa
Jeffrey Martin, Miriam Laker-Oketta, Victoria Walusansa, Jackson Orem, John Bennett, Adrienne Mocello, Toby Maurer, Peter Hunt, Andrew Kambugu, Edward Mbidde

1University of California San Francisco, San Francisco, CA, United States, 2Infectious Diseases Institute, Kampala, Uganda, 3Uganda Cancer Institute, Kampala, Uganda, 4Uganda Virus Research Institute, Entebbe, Uganda

Background: Combination antiretroviral therapy (ART) – including protease inhibitor (PI)-containing regimens – has long been known to decrease lesion burden in some patients with Kaposi sarcoma (KS), but exactly which ART component/mechanism is responsible is unknown. Among the potential explanations, PIs have been speculated to have direct anti-KS effects in humans based on their anti-angiogenesis effects in vitro. We investigated the hypothesis that PI-based ART is clinically superior to PI-sparing ART for the treatment of KS in sub-Saharan Africa, a region where initial ART choice is critical given scarcity of chemotherapy.

Methodology: We enrolled ART-naïve HIV-infected adults with KS in Uganda who had no urgent indications for chemotherapy/radiotherapy. Subjects were randomized to either PI-based (lopinavir/ritonavir plus emtricitabine/tenofovir) or non-nucleoside reverse transcriptase inhibitor (NNRTI)-based ART (efavirenz plus emtricitabine/tenofovir) and observed every 4 weeks for 48 weeks for an indication for chemotherapy and overall survival. Chemotherapy was given free for those who developed an indication post-randomization.

Results: Among 224 subjects randomized (113 PI/111 NNRTI) in this completed trial, 44% were women and median pre-treatment values were: 34 years old, 119 CD4+ T-cells/mm3 and 222,323 copies plasma HIV RNA/ml. Extent of KS was heterogeneous: 7.1% had oral lesions only, 24% had ≥50 skin lesions, and 71% were T1. ART was well tolerated with only 7.1% in the PI arm and 8.1% in the NNRTI arm discontinuing their original drug class. There was no loss to follow-up from the perspective of vital status, and only 3 alive subjects were unavailable for clinical assessment at 48 weeks. A total of 36% of subjects experienced the primary composite outcome (indication for chemotherapy or death) by 48 weeks, but we found no evidence in intent-to-treat analysis for a difference between treatment groups (Fig. 1a). Likewise, for mortality alone, 18% of subjects died by 48 weeks, but we found no treatment differences (Fig. 1b).

Conclusions: Despite biological plausibility, we found no evidence that PI-containing ART was superior to NNRTI-based ART in terms of survival or need for chemotherapy amongst patients with KS who did not initially have urgent chemotherapy indications. The high incidence of subsequent indications for chemotherapy and/or death indicates that ART alone for all comers with KS in Africa is suboptimal and additional interventions are needed.

711 Kaposi Sarcoma in the Era of Combination Antiretroviral Therapy
Natascha Wyss, Matthias Egger, Julia Bohlius, Malignancy Working Group for COHERE in EuroCoord Institute of Social and Preventive Medicine, University of Bern, Bern, Switzerland

Background: Combined antiretroviral therapy (cART) has reduced the risk of developing Kaposi Sarcoma (KS), however, the residual burden of disease remains unclear. We analyzed the data of a large prospective European multi-cohort project, the Collaboration of Observational HIV Epidemiological Research Europe (COHERE) to examine risk factors at enrolment and KS incidence over 15 years of cART availability.
Methodology: We included HIV-infected patients aged >16 years who enrolled in a COHERE cohort after 1.1.1996. We defined cART as a regimen of at least 3 drugs from at least 2 drug classes. Incidence of KS was estimated for patients on cART and not on cART. We calculated incidence rates and ran Cox regression models adjusted for calendar period, age, exposure group, CD4 cell counts, HIV viral load and CDC stage at enrolment (model 1), and origin (model 2). cART was treated as a time-dependent variable. KS cases diagnosed within 30 days after cART start were classified as not on cART.

Results: We included 156,667 patients from 24 cohorts (median age 35 years, 73% male, median CD4 cell count at enrolment 338 cells/μL). 25,564 patients never started any antiretroviral therapy; 23,342 patients started mono- or dual-therapy, which was followed by cART in 17,703 patients; and 107,761 patients started cART being treatment naïve. During 877,920 person-years (pys) 2,090 patients developed KS. The incidence was 393/100,000 pys (95% CI 366-421) among patients not receiving cART and 123/100,000 pys (95% CI 115-133) among patients on cART for more than 6 months (HR 0.21, 95% CI 0.18-0.25; model 1). In the first 6 months of cART, the incidence was 976/100,000 pys (95% CI 89-1070). The risk of developing KS was higher among patients aged > 50 years, among men, men who have sex with men, and patients with low CD4 counts and high HIV viral loads at enrolment (Table 1). However, there was no evidence for an effect of CDC stage at enrolment on the risk of developing KS. KS incidence decreased over calendar years. Model 2 confirms these results and indicates a higher risk for patients of African origin.

Conclusions: In the era of cART the incidence of KS remains high during the first months on cART, possibly because of IRIS. Male patients, particularly men who have sex with men, patients of African origin or aged above 50 years are important risk groups. Patients enrolling into the cohort with uncontrolled HIV viral replication and advanced immunosuppression are also at increased risk of developing KS.

Table 1: Multivariate Cox-regression of the risk of Kaposi sarcoma (KS) in the COHERE collaboration

* Values assessed at the time of enrolment

cART: Combination antiretroviral therapy
**712 Vitamin D Insufficiency in AIDS-Associated Kaposi Sarcoma in Zimbabwe**

Kristine M. Erlanson1, Ivy Gudza2, Suzanne Fiorillo1, Buxton Ndemera2, Robert T. Schooley3, Lovemore Gwanzura2, Margaret Borok2, Thomas B. Campbell1

1University of Colorado Anschutz Medical Campus, Aurora, CO, United States, 2Department of Medicine, University of Zimbabwe College of Health Sciences, Harare, Zimbabwe, 3Infectious Diseases, University of California San Diego, San Diego, CA, United States, 4Department of Medical Laboratory Sciences, University of Zimbabwe College of Health Sciences, Harare, Zimbabwe

**Background:** Low 25-hydroxyvitamin D (25(OH)D) has been associated with progression of some malignancies. The activated form of vitamin D may slow tumor growth in vitro, and topical vitamin D may slow cutaneous KS in persons with localized KS. We hypothesized a high prevalence of 25(OH)D deficiency among persons with AIDS-KS in Zimbabwe, and that baseline 25(OH)D would be associated with AIDS-KS progression.

**Methodology:** 90 antiretroviral naive participants were enrolled in a prospective study of antiretroviral therapy for treatment of AIDS-KS in Harare, Zimbabwe. Co-formulated abacavir, lamivudine, and zidovudine was initiated in all subjects. Chemotherapy or radiation was provided at the discretion of the provider. Subjects were followed for 96 weeks. 25(OH)D was measured from stored plasma samples at study entry and dichotomized as insufficient (<75 nmol/L) or adequate (≥75 nmol/L). Relationship between 25(OH)D and HIV or AIDS-KS clinical response was described by Spearman correlation coefficient for continuous variables and odds ratios and 95% confidence intervals (CI) for dichotomous variables.

**Results:** Samples were available from 85 participants. Median 25(OH)D was 73 (56-89) nmol/L; 45 (53%) had insufficient levels. 25(OH)D insufficiency was associated with higher baseline plasma HIV-1 RNA (4.7 [4.3-5.0] versus 4.5 [3.9-4.9] log10 copies/mL; p=0.04), and baseline 25(OH)D correlated with log change in plasma HIV-1 RNA (r=0.34, p=0.009). No correlation was detected between baseline 25(OH)D and change in CD4+ count (r=0.05, p=0.64), plasma herpeshuman virus (HHV)-8 DNA (r=0.06, p=0.60), or peripheral blood mononuclear cell HHV-8 DNA (r=-0.12, p=0.26). Similarly, baseline and change in CD4+ count, plasma or peripheral blood mononuclear cell HHV-8 viral load were not significantly different between subjects with adequate or insufficient 25(OH)D (all p>0.4). Adequate 25(OH)D was not significantly associated with KS clinical response (OR 0.6; CI 0.2, 1.9; p=0.40), KS-IRIS occurrence (0.4; 0.2, 1.9; p=0.40), chemotherapy initiation (1.2; 0.5, 2.8; p=0.68), radiation initiation (0.6; 0.2, 1.5; p=0.24), or death (0.5; 0.1, 1.9; p=0.30). Odds ratios and significance remained unchanged after adjustment for baseline HIV-1 viral load and CD4 count.

**Conclusions:** Vitamin D insufficiency was common among Zimbaweanes with AIDS-KS. Although we detected a relationship between 25(OH)D levels and plasma HIV-1 RNA responses, baseline 25(OH)D was not associated with other virological, immunological or clinical outcomes during treatment of AIDS-KS. This study does not support a role for vitamin D supplementation in AIDS-KS treatment.

---

**713 Primary Effusion Lymphoma and HIV Infection: 51 Patients From a Single Institution**

Stephanie Guillet1, Laurence Gerard1, 2, Veronique Meignin3, Felix Agbalika4, Wendy Cuccuini5, Lionel Galicier1, 2, Eric Oksenhendler1, 2

1Clinical Immunology, Saint-Louis Hospital, Paris, France, 2EA3963, Université Paris Diderot, Sorbonne Paris Cité, Paris, France, 3Pathology, Saint-Louis Hospital, Paris, France, 4Virology, Saint-Louis Hospital, Paris, France, 5Hematology Laboratory, Saint-Louis Hospital, Paris, France

**Background:** Primary Effusion Lymphoma (PEL) is a rare B-cell non-Hodgkin lymphoma (NHL) that is almost exclusively observed in HIV-infected patients (pts). It accounts for approximately 4% of all HIV-NHL, with a stable incidence in combined antiretroviral therapy (cART) era. Lymphoma cells are always infected with HHV-8 and in most cases coinfected with EBV. In its classic presentation PEL is characterized by body cavity effusions with or without mass lesions. A variant with extracavitary localisation has more recently been described. We report a large single institution series of 51 pts with PEL in the cART era.

**Methodology:** All consecutive HIV-infected pts with a diagnosis of PEL since 1996 were included in the study. The main objective was to describe the characteristics and the outcome of pts with classic and extracavitary variant. Survival was estimated using Kaplan-Meier method, and was tested using the log-rank test.

**Results:** 51 pts were included between Jan 1996 and May 2013; 47 male (92%), median age 45 years. At PEL diagnosis, the median duration of HIV infection was 8 years (IQR, 1.4-15.6). 33 pts had prior AIDS and 35 pts received cART for a median of 40 months. The median CD4 cell count was 204 x 106/L (IQR, 90-370), and 25 pts (49%) had undetectable HIV-RNA. An other HHV-8-associated disease was observed in 30 pts (25 Kaposi sarcoma, 17 multicentric Castleman disease). 34 pts presented classic variant and 17 extracavitary variant. No major difference was observed between the 2 groups in terms of demographic, HIV and lymphoma characteristics. In classic PEL, pleural, peritoneal and pericardial involvement were present in 27, 17 and 12 pts, respectively. Extracavitary PEL was exclusively nodal in 6 patients and involved various organs in the others: GI tract (4), spleen (3), CNS (3), BM (2), liver (2), skin (2), testis, bone, sinus and muscle (1 each). 33 tumors were coinfected with EBV.

All but 2 pts received chemotherapy, including high dose methotrexate in 13 pts. Complete remission was achieved in 28 pts (56%), without difference between the classic and the extracavitary groups (62% vs 41%). After a median follow-up of 10 years, 34 pts have died (29 with lymphoma), providing a median overall survival (OS) of 10.2 months, without difference between the 2 variant groups (P=0.78). The 5-year Overall Survival rate was 42% [95%CI, 27-55%].

**Conclusions:** Based on a large single institution series of 51 PEL, characteristics of classic and extracavitary variants seems to be very close. Despite cART use, control of HIV infection, and treatment with intensive chemotherapy, similar to that used in HIV-uninfected pts, the prognosis remains poor with a median survival below 1 year. However some pts have long-term survival, and the 5-year OS of 42% compares favorably with earlier series.
Indoleamine 2, 3-Dioxygenase (IDO) Activity as a Determinant of Kaposi Sarcoma in Africa

Helen Byakwaga1, 2, Peter W. Hunt1, Miriam Laker-Oketta1, 3, David V. Glidden1, Yong Huang1, Mwebesa Mwebesa2, Victoria Walusansa4, David R. Bangsberg5, Edward Mbidde3, Jeffrey N. Martin6

1University of California San Francisco, San Francisco, CA, United States, 2Mbarara University of Science and Technology, Mbarara, Uganda, 3Infectious Diseases Institute, Kampala, Uganda, 4Uganda Cancer Institute, Kampala, Uganda, 5Harvard Medical School, Massachusetts General Hospital, Center for Global Health, Boston, MA, United States

Background: Other than human herpesvirus 8 (HHV-8) and CD4+ T cell lymphopenia, the mechanisms responsible for Kaposi’s sarcoma (KS) are poorly understood. This is the case both in resource rich areas and in resource poor hyperendemic areas such as sub-Saharan Africa. Additional mechanisms must exist in Africa given the relatively low frequency of KS in HIV infected patients despite the high prevalence of both HHV-8 infection and low CD4+ T cell count. One recently explored pathway of HIV pathogenesis involves induction of the enzyme indoleamine 2,3 dioxygenase (IDO) in dendritic cells, which catabolizes tryptophan into kynurenine and several other immunologically active metabolites that suppress T cell proliferation. We investigated whether IDO has a role in KS etiology.

Methodology: In a case control design, cases were HIV infected adults sampled throughout Uganda, with biopsy confirmed KS and no urgent indications for chemotherapy; they were being seen in preparation for the Antiretrovirals for Kaposi’s Sarcoma (ARKS) clinical trial. Controls without KS were derived from the Uganda Rural AIDS Treatment Outcomes (UARTO) cohort, a consecutive sample of HIV infected adults starting antiretroviral therapy (ART) in southwestern Uganda. All biological tests were performed on pre-ART samples. IDO activity was assessed by the ratio of plasma kynurenine to tryptophan levels (K:T) measured by liquid chromatography tandem mass spectrometry.

Results: We studied 631 subjects: 222 KS cases and 409 non KS controls (Table). Cases had a wide spectrum of mucocutaneous KS ranging from oral lesions only to widespread cutaneous dissemination. In multivariable regression, KS was independently associated with K:T but in a non-linear manner. There was no effect of K:T on KS amongst those in the lower three quartiles, but subjects with the highest quartile of K:T (i.e., highest values) had a 59% reduction in the odds of KS (Table). The relationship between K:T and KS was present at all levels of CD4+ T cell count (p = 0.44 for interaction). KS was also independently associated with lower CD4+ T cell counts, higher plasma HIV RNA levels and men.

Conclusions: Higher IDO activity as evidenced by higher plasma K:T, was protective against the occurrence of KS. This relationship is independent of both plasma HIV RNA level and CD4+ T cell count. The findings are consistent with the hypothesis that lymphocyte proliferation is necessary for the development of KS, which is compatible with the inflammatory nature of KS lesions.

Epidemiology and Dynamics of HPV Infection in Romanian Women Infected With HIV in Early Childhood

Sanjay R. Mehta1, Lumi Enes1, Cristina Voinea2, Claudia Stefanescu2, Diana Sima2, Dan Duciulescu1,2,3
1Medicine, University of California San Diego, La Jolla, CA, United States, 2“Dr. Victor Babes” Hospital for Infectious and Tropical Diseases, Bucharest, Romania, 3Titu Maiorescu University, Bucharest, Romania

Background: Human Papilloma Virus (HPV) is the most common sexually transmitted virus worldwide and the most common cause of cervical cancer. Romania, where cervical cancer screening is not standard of care, has the highest rate of cervical cancer in Europe. Here we evaluate the prevalence and dynamics of HPV infection in a cohort of Romanian women in their early 20s who were parenterally infected with HIV during early childhood.

Methodology: 65 young women with chronic HIV infection and 25 age-matched controls were evaluated for the presence of cervical HPV infection and for cytologic abnormalities. HPV typing was performed using the Linear Array HPV Genotyping Test (Roche). Individuals were screened for other sexually transmitted infections, and HPV data was obtained from patients’ charts. Risk factors for HPV infection and socio-demographic information were also obtained. 42 subjects were seen at two or more time-points. Statistical comparisons using standard approaches were made between the HIV infected (HIV+) and uninfected (HIV-) groups at baseline, and between HIV+ individuals with and without HPV infection.

Results: Although the HIV- and HIV+ groups were fairly similar, HIV- individuals had more years of schooling, were less likely to be on social support, and were more likely to use barrier contraception (p<0.056). 43% (28/65) of HIV+ and 32% (8/25) of HIV- subjects were infected with HPV, and 21/65 and 6/25 had high risk subtypes respectively. There was no significant difference between HIV+ (14) and HIV- (5) subjects in terms of having HPV infection with more than one strain (p=NS). Using our longitudinal data, we found an incidence rate of 0.69 HPV acquisition events per subject per year, and a rate of 0.52 for high risk subtypes. In individuals sampled more than once, those having maintaining or acquiring a new subtype in follow up were more likely to have a lower nadir CD4 count (p=0.043) and a lower current CD4 count (p=0.010). In the HIV+ group, of 13 individuals with abnormal cytology at baseline, nine (69.2%) progressed or remained stable while only four regressed.

Conclusions: We describe here HPV infection in a unique group of young women infected with HIV during early childhood, acquiring HPV in the setting of long-term HIV infection. Although HPV prevalence was only slightly higher among the HIV+ group, possibly due to differences barrier contraception use, the decreased ability of HIV infected young women to mount new immune responses predisposed them to HPV progression and Pap smear abnormalities. Given the high rate of HPV acquisition, and progression of abnormal cytology in this cohort, HPV vaccination even at this stage may be useful.

Baseline Data of a Phase 3 Trial of the Quadravalent HPV Vaccine in HIV+ Males and Females: ACTG 5298

Ross Cranston1, Ming Yang2, Pawel Paczuski2, Michelle Cespedes2, Elizabeth Chiao3, Jennifer Webster-Cyriaque4, Catherine Godfrey4, Timothy Wilkin5
1University of Pittsburgh, Pittsburgh, PA, United States, 2Harvard University, Cambridge, MA, United States, 3New York University School of Medicine, New York, NY, United States, 4Houston VA Medical Center, Houston, TX, United States, 5University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 6DAIDS, NIAID, NIH, Bethesda, MD, United States, 7Weill Cornell Medical College, New York, NY, United States

Background: Human papillomavirus (HPV) is the main cause of anogenital and oropharyngeal squamous cell cancer. The prophylactic quadrivalent HPV vaccine (qHPV 6, 11, 16, 18) is indicated for males and females aged 9-26 years. A5298 is an ongoing randomized placebo controlled phase 3 study of the qHPV vaccine to prevent anal HPV infection.

Methodology: Entry Criteria: HIV+ females and males who have sex with males; ≥ 27 years old; no history of anogenital or oral cancer; ACTG sites with certified high resolution anoscopy (HRA) providers. Two baseline anal and oral specimens for HPV genotyping by polymerase chain reaction were collected. Anal cytology and HRA with or without biopsies were performed. Half of the females were required to have anal high grade squamous intraepithelial lesions (HSIL) at screening. The chi-square test was used to assess the association between HPV infection and HSIL status at baseline with no adjustment for co-infections. All statistical tests were performed at the 0.05 level without adjustment for multiple comparisons.

Results: 575 participants (ppts) were enrolled (82% male and 18% female). Median age was 47 years. Race/ethnicity was 45% White, 31% Black and 21% Hispanic. Plasma HIV RNA was <50 copies/mL in 84% and median CD4 count was 606 T cells/μL. Any abnormal anal cytology was detected in 61%. High-grade SIL was detected on biopsy in 33%. Anal HPV 6, 11, 16 and 18 was detected in 24%, 13%, 32%, and 18% of ppts respectively. The simultaneous prevalence of 0, 1, 2, 3, 4 qHPV vaccine types was 41%, 38%, 17%, 4%, and 1% respectively. The prevalence of types 31, 33, 45, 52 and 58 ranged from 12% to 24%. Types 16, 18, 31, 45, and 58 were significantly associated with detection of HSIL (p-values <.01). Types 11, 33, 52 were marginally associated with HSIL (p-values .05 to .1). Table 1. In males (n=343), oral infection with HPV 6, 11, 16 and 18 was present in 2%, 3%, 3%, and 2% of ppts respectively, with ≥ 1 quadrivalent HPV type detected in 27 (8%) ppts.

Conclusions: In this trial population with well controlled HIV infection, there was a high proportion of abnormal anal cytology, HSIL on anal biopsy, and anal HPV infection. However, less than one-quarter of ppts had more than one anal qHPV type detected, and could theoretically derive protection from the qHPV vaccine. The proportion of oral HPV in this population was low. The investigational nonavalent vaccine (qHPV 31, 33, 45, 52, and 58) is in late stage clinical development and should offer even broader prevention of anal HSIL.
**717  Cervical Abnormalities in HIV-Infected South African Women With High Screening and Referral Rates**

Ingrid T. Katz 1, 2, Aloxi A. Wright 1, 3, Tamaryn L. Crankshaw 4, 5, Janet Giddy 4, 6, Sean Mould 4, 7, Lisa M. Butler 2, 8

1 Medicine, Brigham and Women's Hospital, Boston, MA, United States, 2 Harvard Medical School, Boston, MA, United States, 3 Dana Farber Cancer Center, Boston, MA, United States, 4 McCord Hospital, Durban, South Africa, 5 Health Economics and HIV/AIDS Research Division, Durban, South Africa, 6 University of Cape Town, Cape Town, South Africa, 7 Gynaecology and Obstetrics, R. N. Kahn Hospital, Chatsworth, South Africa, 8 Boston Children's Hospital, Boston, MA, United States

**Background:** Access to antiretroviral therapy (ART) has improved in South Africa (SA), enabling HIV-infected women to live longer and healthier lives. However, they remain at increased risk of mortality from cervical cancer, the leading cause of cancer-related deaths. This study aims to advance our understanding of the prevalence of screening, cervical dysplasia, and histologic diagnoses from colposcopy and large loop excision of the transformation zone (LLETZ) in a high HIV prevalence region of SA.

**Methodology:** We performed a retrospective cohort study to determine the prevalence of cervical dysplasia and malignancy among HIV-infected women attending an urban ART clinic in KwaZulu-Natal (KZN), SA over a five-year period (2004-2009). A random sample of eligible women defined as HIV-infected, >18 years old, and attending the clinic for >3 months--enrolled in HIV-care was included from each study year. Data were abstracted from electronic records and paper charts, including date of birth, CD4+ count, viral load (VL), initial Pap smear results, colposcopy and LLETZ results. Per clinic guidelines, colposcopy/LLETZ was indicated for women with two consecutive LSIL's or a single HSIL Pap smear. We also tracked time to colposcopy among women with abnormal Pap smears.

**Results:** We reviewed charts of 462 women with median age 33.7 years (IQR 29.0-39.2 years), median baseline CD4 117.5 (IQR 55-177), median baseline VL 49 (IQR 24-61). 432 (93.3%) had at least one evaluable Pap smear over the study period and 330 (76%) had two or more Pap smears (median=3, IQR 2-4). At baseline, 237 (54.9%) women had an abnormal Pap smear (see Table). 103 women were referred for colposcopy, of whom 89/103 (86.4%) had documentation of completed colposcopy within a median of 39 days (IQR 20-119 days) of referral yielding 57/89 (64.0%) evaluable samples of which 21.1%, 28.1%, 26.3%, and 1.8% had cervical intraepithelial neoplasia (CIN) I, CIN 2, CIN 3, and invasive cervical cancer, respectively.

**Conclusions:** Among a sample of HIV-infected women in an urban clinic in KZN, SA where Pap smear coverage and rates of referral for colposcopy/LLETZ were very high, we observed a prevalence of >75% cervical dysplasia and malignancy among those referred. These findings support the importance of cervical screening upon entry into care, and suggest that all HIV-infected women with cytological abnormalities on Pap smear should undergo early evaluation with colposcopy to minimize loss to care and optimize chances for survival.

**Anal Cancer and HPV**

**718  Prevalence of Anal Dysplasia in HIV-Infected Women From Johannesburg, South Africa**

Bridgette Goeieman 1, 2, Cynthia Finnhaber 1, 2, Pamela Michelow 1, 3, Avril Swarts 1, Jennifer S. Smith 4, Timothy Wilkin 2

1 University of Witwatersrand, Johannesburg, South Africa, 2 Right to Care, Johannesburg, South Africa, 3 National Health Laboratory Services, Johannesburg, South Africa, 4 University of North Carolina, Chapel Hill, NC, United States, 5 Weill Cornell Medical College, New York, NY, United States

**Background:** Cervical cancer caused by oncogenic Human Papillomavirus (HPV) infection is a common cause of morbidity and mortality in HIV-infected women in Sub-Saharan Africa. HPV infection also causes anal cancer, but the incidence of anal cancer in this population is unclear. In Sub-Saharan Africa, there are no known data available on the prevalence of anal HPV infection or dysplasia in HIV-infected individuals. These are the first epidemiological data on the prevalence of anal HPV infection and dysplasia in HIV-infected women from South Africa.
**Methodology:** Prospective cohort study of HIV-infected women age 25-65. Participants were recruited from an HIV clinic in Johannesburg, South Africa. Anal swabs were taken for conventional glass-slide cytology and oncogenic HPV testing (Digene HC2). All women with abnormal anal cytology and 20% of women with normal cytology were seen for high resolution anoscopy (HRA) with biopsy of visible lesions. Biopsies were taken at the 6 and 12 positions on anus for women with visible lesions. Women had cervical cytology and HPV specimens obtained. We summarized the baseline characteristics of this cohort using descriptive statistics. Quality assurance of HRA was done through digital pictures and discussion with a specialist.

**Results:** A total of 88 women have been enrolled. The anal cytology results were normal in 9/88 (10%); 61/88 (69%) had low grade squamous intraepithelial lesions (SIL), and 16/88 (20%) had high grade SIL. 84% of women had an abnormal cervical cytology defined as low grade lesions and above. Anal biopsies results are available for 48 women: 23 (48%) had negative histology, 9 (19%) had atypia, 11 (23%) had low-grade lesions anal intraepithelial neoplasia (AIN) and 5 (10%) had High Grade AIN. 45% of women had high risk HPV detected on anal swabs, and 36% had high risk HPV on cervical swabs. Anal high risk HPV was found in 34% of women with LSIL on anal cytology and 75% of women with HSIL anal cytology.

**Conclusions:** We have found significant burden of anal HPV infection and abnormal anal cytology. High grade (SIL) on anal cytology was found in 20% of our women which is 2-4X higher than reports from cohorts of men who have sex with men. The observed prevalence of high grade AIN was lower given the cytology reports, and correlation may improve with more provider experience. Further studies should evaluate with rate of anal cancer in HIV-infected women in sub-Saharan Africa. HPV vaccination programs and anal cancer screening should be considered.

---

**719 Mucosal and Systemic Immune Responses in HIV/HPV Co-Infected Males**

Laura Comi1, Camilla Tincati1, Giusi Maria Bellistrì1, Alessandro Pandolfi1, Javier Sanchez Martinez2, Veronica Rainone2, Marco Rovati2, Daria Trabattoni2, Antonella d’Arminio Monforte1, Giulia Marchetti1

1Department of Health Sciences, Clinic of Infectious Diseases, San Paolo Hospital, Milan, Italy, 2Departments of Biomedical and Clinical Sciences “L. Sacco” and of Physiopathology and Transplantation, University of Milan, Milan, Italy, 3Department of Health Sciences, Surgery Chair, “San Paolo Hospital.” University of Milan, Milan, Italy

**Background:** We investigated anal inflammation, systemic T cell phenotype activation, and HPV-specific immunity in HIV HPV coinfected patients (pts) with and without HPV driven dysplasia and the association with HPV disease progression or clearance at anal site.

**Methodology:** We enrolled HIV+ men who underwent anorectal swabs for HPV-PCR detection/genotyping (High Risk HR) and cytologic abnormalities (Bethesda 2001: Low and High Grade Squamous Intraepithelial Lesions, L-HSIL). A subgroup was re-examined at a 18 months follow-up (FU) visit. The following parameters were measured at baseline (BL) and associated with anorectal cytology at FU: TNFα/IFNγ mRNA at anal site by RT-PCR; CD4/CD8 T cell activation (CD25, CD25/HLDRI, CD45R0, CD38/CD45R0), maturation (CCR7/CD45RA) and cytokine production (IL2, IFNγ, TNFα, granzyme, perforine) following HPV (type 16) specific stimulation were measured by flow cytometry on PBMCs. Mann-Whitney and χ-square test were used.
Results: 40 pts were studied. 27 pts had SIL (26 LSIL) at BL while 13 had normal cytology. No differences were found in immune parameters between the two groups (Fig). 29/40 pts underwent a FU visit. 21/29 were diagnosed HR HPV and LSIL at BL. At FU, 13/21 displayed persistence of LSIL (non-regressors, nR), 6/21 normalised cytology (regressors, R), 2/21 had inadequate results. At BL, R pts displayed higher naive CCR7+ T cells (6.45% IQR 1.9-7.6 vs 1.8% IQR 0.4-3.4, p=0.05) and significantly more activated CD45RO+CD8+ (19.45% IQR 8.1-22.2 vs 7.2% IQR 3.7-15.7, p=0.02) and CD38+CD45RO+CD8+ (10.8% IQR 7.6-17.6 vs 3.9% IQR 2.05-12.5, p=0.03) compared to nRs. Interestingly, nRs were characterized by a significant increase in CD4/CD8 single-positive (CD4+IL2+, CD4+IFNγ+, CD8+TNFα+, CD8+IFNγ+), and double-positive (CD4+IL2+IFNγ+, CD8+TNFα+IFNγ+) cells upon HPV-specific stimulus (Fig), whereas no effect of HPV stimulation was displayed by R pts. At mucosal level, R pts tended to show higher anal TNFα (2.92% IQR 0.8-6.6 vs 0.53% IQR 0.19-2.8, p=0.03) and IFNγ transcripts (2.81% IQR 1.2-9.1 vs 0.57% IQR 0.2-1.8, p=0.08) compared to nR pts.

Conclusions: In HIV/HPV pts, clinical regression of HPV-related anal SIL seems to correlate with heightened local inflammation, systemic T cell activation and expansion of naïve lymphonode homing CCR7+ cells. These findings suggest efficacious immunity at the site of injury, that is not seen in patients with persistent dysplasia despite ex vivo reactivity to an HPV specific trigger.

Natural History of HIV-Related Anal Dysplasia: A Multi-State Modeling Analysis
Wolfgang A. Agmas1, Edward R. Cachay2, Christopher Jackson2, Wm. Christopher Mathews1
1 Internal Medicine, University of California San Diego, La Jolla, CA, United States; 2 Public Health, Medical Research Council Biostatistics Unit, Cambridge, United Kingdom

Background: The natural history of anal intraepithelial neoplasia (AIN) in the absence of treatment is incompletely understood. High grade AIN (HGAIN) is believed to be the precursor lesion for progression to invasive anal cancer (IAC), but rates of progression and regression of HGAIN are not known with precision. The aim of this study was to estimate progression and regression rates of HGAIN in the absence of treatment in a cohort of HIV-infected adults using multistate modeling.

Methodology: Retrospective cohort analysis of HIV-infected patients under care at UCSD Owen Clinic between 2003-2012. Inclusion criteria for multistate analysis: (1) confirmed HIV infection; (2) at least 2 anal cytology (Pap) results if no diagnosis of IAC OR at least 1 cytology result if subsequently diagnosed with IAC. Patients diagnosed with IAC within 180 days of the 1st anal cytology were excluded from multistate analysis. Cytology results were censored after the 1st treatment for AIN and if they were measured ≤180 before IAC diagnosis. Cytology transition probabilities (corrected for misclassification based on cytology sensitivity & specificity) for 3 states (<HGAIN, HGAIN, IAC) were estimated using the msm package implemented in R.

Results: During the study period, 2804 patients underwent ≥2 Paps (or 1 Pap + diagnosis of IAC) (median range: 3 [1-18]). Median IQR followup was 3.9 [1.9-6.9] years. Baseline characteristics: 89% male, 38% non-white, 75% on ART, 49% viral load <400 c/ml; median [IQR]: age 40 [34-46], cd4 384 [217-572]. Of the 41 patients subsequently diagnosed with IAC, 23 were diagnosed >180 days after the 1st cytology result and were included in the multistate model. Confirmatory biopsy results were available for 22/23 (96%). The distribution of person-time followup by selected covariates was: (1) on antiretroviral therapy (88%); (2) HIV viral load ≤400 (71%); (3) smoking (30%). The table presents estimated 2-year HGAIN progression and regression probabilities.

Conclusions: HGAIN regression within 2 years was estimated to vary between 27 - 62% (depending on assumptions regarding cytology accuracy), while progression to IAC was rare (1-2.2%). Initial observation without HGAIN treatment may be a reasonable option, assuming regular followup is assured.

Antiretroviral Therapy as Protector Factor of Anal Dysplasia in HIV-Infected MSM
Carmen Hidalgo Tenorio1, Concepcion Gil Anguita1, Jessica Ramirez Taboada1, Juan Gabriel Martinez Cara2, Javier Esquivias3, Pablo Palma1, Mar Rivero1, Rosario Javier Martinez3, Miguel Angel Lopez Ruiz1, Juan Pasquau Lliao3
1 Infectious Diseases Unit, University Hospital Virgen de las Nieves, Granada, Spain; 2 Gastroenterology Service, University Hospital Virgen de las Nieves, Granada, Spain; 3 Pathology Service, University Hospital Virgen de las Nieves, Granada, Spain; 4 General Surgery Service, University Hospital Virgen de las Nieves, Granada, Spain

Background: Studies show higher incidences of anal carcinoma and faster progression in HIV-infected MSM patients. Chronic infection with oncogenic HPV is associated with the development of anal dysplasia. Antiretroviral therapy (ART) has been shown to decrease the incidence of cervical carcinoma in woman living with HIV; however, so far in the majority of publications ARV has not proven beneficial effect in the appearance of anal dysplastic lesions, except in the Swiss cohort. Objectives: 1-Analyze the role of ARVs in the prevalence of high-grade anal intraepithelial neoplasia (HGAIN) and/or anal cancer in our cohort of HIV positive MSM. 2-Examine the prevalence of anal dysplastic lesions and HPV genotypes in our cohort. 3-Evaluate the risk factors associated with the appearance of HGAIN and/or anal cancer.

Methodology: A cross-sectional study of an HIV-positive MSM cohort. Epidemiological (condylomatosus, sexual habits, use of condom, smoking, alcohol consumption, Other infections, etc), clinical (months since HIV diagnosis, HIV stage according to CDC criteria, ART, virological failure), and analytical (Cd4, HIV viral load, ART efficacy, CD4/CD8 ratio, CD8+T-cells, other infections, etc) data were collected. 276 HIV-1 infected MSM between 19 and 58 years of age (average 40 years) were included. Data were obtained at baseline (BL) and follow-up (FU) visits. Conclusions: Patients receiving ART had lower incidence of HGAIN (2.6%) than patients not receiving ART (6.6%). The results suggesting that ART is protective against anal dysplasia in HIV-infected MSM warrant further investigation.
Viral load (VL), CD4 nadir) data were collected. Two anal mucosa samples were taken and sent for HR-HPV PCR testing and cytology. Anoscopy was then performed for histological samples. The Bethesda cytological system and Richardson's histological classification were used.

**Results:** 140 patients were enrolled, with an average age of 37 years, CD4 nadir 356.3 cell/μL; 77.1% were treated with ARV, currently CD4 652.9 cell/μL, and Viral load 3.83 log; 6% had virological failure. Of 140 anoscopy procedures performed, 35.7% were normal, 47.1% were AIN1, 14.3% AIN 2/3, and 8.6% carcinoma in situ. 74.2% had high-risk (HR) HPV genotypes, 59.7% low-risk (LR) genotypes and 46.8% both. Logistic regression highlighted ARV as a protective factor against ≥ AIN2 lesions (OR: 0.214; 95%CI: 95%: 0.054-0.84). Anal/genital condylomas (OR: 4.26; 95%CI: 1.27-14.3), and HPV68 genotype (OR: 10.6; 95%CI: 1.23-91.47) were identified as risk factors.

**Conclusions:** In our cohort of HIV patients MSM, the antiretroviral therapy has a protective effect against the development of dysplastic anal lesions. 1/6 patients from our cohort has HGAIN, 1/11 has Carcinoma in situ, and 3/4 of them are infected with HR-HPV genotypes. The finding of anal or genital warts, and HPV-68 genotype in anal mucosa are two predictors of HGAIN and/or carcinoma in our cohort of HIV-MSM. This result requires further testing for confirmation of the finding.

### 722 HPV16-Specific T-Cell Responses and Spontaneous Regression of Anal Intraepithelial Neoplasia

**Winnie W. Y. Tong1, Kelee Shepherd1, Fengyi Jin2, John Zaunders3, Richard J. Hillman1, Andrew E. Grulich1, Anthony Kelleher1, 2, Andrew Carr3**

1Centre for Applied Medical Research, St Vincent’s Hospital, Darlinghurst, NSW, Australia, 2The Kirby Institute, Sydney, NSW, Australia

**Background:** 85% of anal cancers are attributable to persistent human papillomavirus type 16 (HPV16) infection. The anal cancer precursor, high grade anal intraepithelial neoplasia (AIN), is common (prevalence >30%) in MSM. High grade disease frequently regresses spontaneously. We hypothesized that T cell immune responses may contribute to its regression.

**Methodology:** We measured systemic T cell responses to HPV16 oncogenic proteins E6 and E7 (synthesized as overlapping peptides) in a substudy of the Study of the Prevention of ANal Cancer (SPANC). This is a natural history study of anal HPV and AIN in MSM aged ≥35 years, in which anal Papillomoccau smears and high resolution anoscopy (with biopsy of visually abnormal lesions) are performed at five visits over three years. At one visit, peripheral blood was taken for a novel assay for CD4 antigen-specific T cells based on CD25/CD134 co-expression after 44 hours culture, and an intracellular cytokine stain (ICS) assay for interferon-γ (IFNγ) and interleukin-2 (IL2) from CD4 and CD8 antigen-specific T cells. For both assays and each participant, negative and positive (staphylococcal enterotoxin B, cytomegalovirus lysate ± CEF peptides) controls were used. A positive response was defined as stimulation index ≥2 and an absolute cell count ≥20 for CD25/CD134 assay (or ≥15 for ICS assay) after subtracting background. Absolute T cell counts were measured with TruCount® tubes. High grade disease was HSIL on cytology and/or AIN2/3 on histology. We tested for associations using Pearson chi2 tests.

**Results:** See table for descriptive results. In cross-sectional analyses, 32.3% of HIV+ men had CD8 T cell responses (IFNγ and/or IL2) to E6 vs. 14.6% of HIV-negative men (p = 0.027). 23.5% of men with high grade disease had IFNγ CD8 T cell responses to E7 vs. 9.6% of men without (p = 0.028).

Using longitudinal cytology / histology data from the main study, 26 men had high grade disease at study entry a mean 1 year prior, of which 6 experienced spontaneous regression by the time these assays were performed. Five (83%) of these 6 regressors had CD4 T cell responses to E6 on the CD25/CD134 assay vs. 35% of non-regressors (p = 0.037). ICS responses (CD4 or CD8) did not associate with regression.

**Conclusions:** Systemic HPV16-E6 and E7-specific T cell responses were detected in a substantial proportion of MSM. E7-specific CD8 T cell responses were more likely in those with high grade disease. E6-specific CD4 T cell responses were associated with recent high grade AIN regression.

Elevated NT-proBNP Levels Predict Mortality in HIV-Infected Women

Matthew R. Gingo1, Kidane Ghebrehawariat1, Jong-Hyeon Jeong1, Yanxia Chu1, Guanwei Yang1, Lorrie Lucht1, David Hanna2, Jason Lazaar3, Mark Gladwin1, Yingze Zhang4, Alison Morris5

1University of Pittsburgh, Pittsburgh, PA, United States, 2Albert Einstein College of Medicine and Montefiore Medical Center, Bronx, NY, United States, 3SUNY Downstate Medical Center, Brooklyn, NY, United States, 4University of Pittsburgh, Pittsburgh, PA, United States

Background: Cardiovascular and pulmonary diseases are common comorbidities in HIV-infected individuals. Elevated N-terminal-pro-brain natriuretic peptide (NT-pro-BNP) is a marker of cardiac ventricular strain and systolic dysfunction and has been previously been shown to be associated with comorbidities in HIV. We aimed to determine if elevated NT-pro-BNP was associated with greater mortality in HIV-infected individuals.

Methodology: NT-pro-BNP was measured from stored serum samples from a random sample of half the HIV-infected and matched on age (1:2) HIV-uninfected participants in the Women’s Interagency HIV Study at two time periods: early anti-retroviral therapy (ART) (10/11/94 to 7/17/97) and late ART (4/1/08 to 10/7/08). The proportion of participants with NT-pro-BNP levels >75th percentile were compared by HIV status at each time point. Cox proportional hazards models were used to determine if an elevated NT-pro-BNP was associated with mortality independent of other covariates (age, race, body mass index, smoking status, alcohol use, illicit drug use, hepatitis C serostatus, hypertension, renal function, hemoglobin, history of AIDS, antiretroviral use, CD4 count, and viral load).

Results: There were 387 HIV-uninfected and 936 HIV-infected and 1082 HIV-infected in the early and late ART periods, respectively. HIV infection was not associated with a NT-pro-BNP level in the early period, but HIV-infected persons were more likely to have a NT-pro-BNP level in the highest quartile in the late period (26.6% vs. 21.2%, unadjusted p=0.03). In HIV-infected participants, NT-pro-BNP>75th percentile was independently associated with worse survival in the 5 years subsequent to the date the sample was drawn in both the early (HR 1.8, 95% CI 1.3-2.4, p<0.001) and late (HR 2.8, 95% CI 1.4-5.5, p=0.002) periods. The NT-pro-BNP level was not associated with mortality in HIV-uninfected women in the early period, and in the late period, there were too few deaths in the HIV-uninfected group to assess an association.

Conclusions: We have identified NT-pro-BNP as a novel independent predictor of mortality in HIV-infected women. As NT-pro-BNP is often associated with cardiopulmonary dysfunction, these findings suggest that these conditions may contribute to adverse outcomes in this population.
ST2 and GDF-15 Are Associated With Structural Heart Disease and Mortality in HIV

Eric Secemsky1, Rebecca Scherzer2, Elaine Nitta2, Alan Wu2, David Lange2, Steven Deeks2, Jeffrey Martin2, James Snider2, Peter Ganz2, Priscilla Hsue2
1UCSF, San Francisco, CA, United States, 2University of California San Francisco, San Francisco, CA, United States

**Background:** HIV-infected individuals have a high rate of cardiovascular disease, and traditional factors do not fully identify at-risk patients. We studied whether biomarkers of inflammation, cardiac stress and renal function are associated with structural heart disease and overall mortality in ambulatory HIV patients.

**Methodology:** Serum biomarkers (ST2, NT-proBNP, GDF-15, Cystatin C, IL-6, D-Dimer, ultrasensitive Troponin I, hscRP) and echocardiograms were assessed in 332 HIV patients and 50 controls in 2004-2011. We defined systolic dysfunction as ejection fraction <50%, and diastolic dysfunction as ≥ stage 1. Mortality data was obtained through the National Death Index.

**Results:** HIV patients were a median age of 49 years, 80% male, 34% hypertensive, 59% dyslipidemic, and 35% smokers. Sixty eight percent were treated with undetectable viral loads. Compared to controls, HIV patients had higher levels of all biomarkers except IL-6 (p<0.05 for all). Among HIV patients, 45% had diastolic dysfunction (DD); only ST2 was associated with DD in fully-adjusted analysis (RR=1.43 per doubling, 95%CI 1.06-1.92, p=0.019). Systolic dysfunction was rare in this cohort and showed no association with the candidate biomarkers. Thirty-three deaths occurred among HIV subjects over a median 5.8 years. In fully-adjusted analysis, only ST2 (HR 1.89, 95%CI 1.04-3.44, p=0.036) and GDF-15 (HR 1.35, 95%CI 1.02-1.79, p=0.038) were individually associated with mortality. Using ROC analyses, thresholds > 40 ng/ml for ST2 and 1665 pg/ml for GDF-15 were each predictive of mortality. This association was strengthened when both thresholds were surpassed (see figure).

**Conclusions:** Among HIV patients, ST2 and GDF-15 were associated with mortality risk. ST2 was also associated with diastolic dysfunction. ST2 and GDF-15 may be useful biomarkers of CV risk and overall mortality in HIV.

Depression and HIV Are Risk Factors for Incident Heart Failure Among Veterans

Jessica R. White1, Chung-Chou H. Chang2, Adeel A. Butt3, Hilary A. Tindle4, Maria C. Rodriguez Barradas4, David Rimland5, David Leaf6, Matthew Budoff7, Amy C. Justice8, Matthew S. Freiberg9
1University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA, United States, 2University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 3Veteran Affairs Pittsburgh Healthcare System, Pittsburgh, PA, United States, 4Baylor College of Medicine, Houston, TX, United States, 5Michael E. DeBakey Veteran Affairs Medical Center, Houston, TX, United States, 6Emory University School of Medicine, Atlanta, GA, United States, 7Atlanta Veteran Affairs Medical Center, Atlanta, GA, United States, 8David Geffen School of Medicine, Los Angeles, CA, United States, 9Veteran Affairs Greater Los Angeles Health Care System, Los Angeles, CA, United States, 10Veteran Affairs Connecticut Health Care System, West Haven, CT, United States, 11Yale University School of Medicine, New Haven, CT, United States

**Background:** HIV infection is associated with an increased risk of heart failure (HF). Depression, a common comorbidity among HIV infected (HIV+) and uninfected (HIV-) people, is also associated with HF. The high prevalence of clinical depression among HIV+ adults is concerning due to increased risk of HF among HIV+ people. This study examined the association between depression and HF in a large cohort of HIV+ and HIV Veterans.

**Methodology:** We analyzed data on 81,427 Veterans (33% HIV+) without prevalent cardiovascular disease (CVD) from the Veterans Aging Cohort Study - Virtual Cohort (VACS VC), a prospective study of HIV+ and their age-, sex-, race/ethnicity- and clinical site-matched HIV Veterans. Veterans were followed from their first clinical encounter on or after 4/1/2003 until a HF event, death, or their last follow-up date (12/31/2009). Using baseline diagnoses of Major Depressive Disorder (MDD, ICD-9 codes 296.2x & 296.3x), participants were categorized into 4 groups: HIV without depression (referred), HIV with depression; HIV+ with depression; and HIV+ with depression. HF was determined using VA and Medicare ICD-9 codes (428.xx, 429.3, 402.01, 402.11, 402.91, 425.xx). Cox proportional hazards regression was used to model the association between depression, HIV-infection, and incident HF, adjusting for demographics, serum lipids, smoking, blood pressure, diabetes, renal disease, obesity, hepatitis C, atrial fibrillation, and atrial flutter, and substance use. Secondary analysis restricted the assessment to include only HIV+ patients, adjusting the same covariates plus HIV-specific risk factors.
Results: During a median of 5.9 years of follow-up, there were 2666 HF events (38% HIV+). HF rates per 1000 person-years and risks adjusting for covariates are presented in Table 1 by HIV status and MDD diagnosis. Compared to Veterans without either condition, those with only MDD, with only HIV, or with both HIV and MDD were at higher risk for incident HF (Table 1). Among HIV+ Veterans, MDD remained a significant risk factor for HF after adjusting for covariates in Table 1 and baseline ART regimen, CD4 count, and viral load (HR(95%): 1.30 (1.11 - 1.51)) and with recent (i.e., within 6 months of event) ART regimen, recent CD4 count, and recent viral load (HR(95%): 1.27 (1.09 - 1.48)).

Conclusions: Depression is associated with an increased risk for incident HF regardless of HIV status. Among those with HIV, depressed Veterans had higher rates of HF compared to those without depression.

Impact of Low CD4 Count and HIV Persistence On Endothelial Function in Patients With Low Plasma RNA
Amanda Schnell Heringer1, Hiroyu Hatano2, Peter W. Hunt1, Yuenan Wu1, Yifei Ma1, Rebecca Scherzer3, Jeffrey N. Martin1, 4, Peter Ganz4, Steven G. Deeks2, Priscilla Y. Hsue1
1Division of Cardiology, San Francisco General Hospital, University of California San Francisco, San Francisco, CA, United States, 2Positive Health Program, University of California San Francisco, San Francisco, CA, United States, 3Division of Adolescent Medicine, University of California San Francisco, San Francisco, CA, United States, 4Veterans Administration Medical Center, University of California San Francisco, San Francisco, CA, United States, 5Veterans Administration Medical Center, San Francisco, CA, United States, 6Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA, United States

Background: Chronic inflammation contributes to increased cardiovascular (CV) risk among HIV-infected individuals with low plasma viral RNA levels. Hyperemic velocity (HV), a measure of microvascular function, is the stimulus for brachial artery flow-mediated vasodilation (FMD), a measure of macrovascular function. HV is more predictive of CV events than FMD in the general population. The contribution of HIV persistence and traditional CV risk factors to microvascular and macrovascular dysfunction has not previously been evaluated.

Methodology: We studied 71 HIV-infected individuals. Endothelial function was assessed using FMD. HV was measured as peak velocity-time integral (VTI) of the first complete velocity envelope after cuff release. D-dimer, hs-CRP, IL-6, sCD14, sCD163, and TNF-α were also measured. HIV persistence was determined using ultrasensitive plasma HIV RNA (lower limit of detection <0.3 copies/mL, single copy assay), total proviral DNA in PBMCs (copies/million CD4+ T-cells), and cell-associated RNA in PBMCs using TMA assay (signal/cutoff per million CD4+ T-cells). Multivariate Poisson regression was used to determine predictors of HV and FMD.

Results: Most participants were male (96%) with a median age of 51 years. Approximately 30% had traditional CV risk factors. Based on conventional assays, 72% were treated and suppressed while 28% were untreated elite controllers. The median CD4+ T-cell count was 554 (IQR 314-741). The median plasma RNA using single copy assay was 0.8 copies/mL; 63% had <0.3 copies/mL plasma RNA. The median cell-associated RNA level was 5.6 (IQR 3.8-6.8) and the median proviral DNA level was 1.75 (IQR 1.1-2.5) log10 S/C per million CD4+ T-cells, respectively. The median HV was 85 cm (IQR 57.8-100.7) and the median FMD was 4.8% (IQR 2.9-5.7). Worsened HV was independently associated with lower CD4+ T-cell count (RR 1.04 per 100 CD4+ T-cells, p<.001). In contrast, lower eGFR (RR 1.72, p=0.002), smoking (RR 1.25, p=0.039), and higher cell-associated RNA (RR 0.95, p=0.045) were associated with impaired FMD after adjustment for age and gender. Inflammatory and coagulation markers were not significantly associated with FMD or HIV. Among treated and suppressed individuals only, lower eGFR and smoking remained significantly associated with impaired FMD while the association with cell-associated RNA weakened.
**Conclusions:** Among HIV-infected subjects with low plasma RNA levels, a low CD4+ T-cell count was associated with impaired HV, while traditional risk factors and cell-associated HIV RNA levels were associated with worsened FMD. Our findings suggest that HIV may preferentially affect the microvasculature leading to endothelial dysfunction. Therapies targeted at further reduction of HIV persistence may also decrease CV risk.

**728 Carotid Distensibility and Immune Activation in HIV-Infected Patients Without Coronary Calcium**

Chris T. Longenecker1, Ying Jiang1, Sara Debanne1, Grace A. McComsey1, 2

1Case Western Reserve University, Cleveland, OH, United States, 2University Hospitals Case Medical Center, Cleveland, OH, United States

**Background:** Coronary artery calcification (CAC) scoring significantly improves cardiovascular risk stratification; however, CAC is a late finding of atherosclerotic vascular disease. Increased vascular stiffness (i.e., decreased distensibility) may be an early marker of vascular disease in HIV-infected patients on antiretroviral therapy (ART) prior to the development of vascular calcification. The relationship of chronic systemic immune dysregulation to these early vascular changes in HIV is poorly understood.

**Methodology:** High-resolution carotid ultrasound was used to examine common carotid artery intima-media thickness (CCA-IMT) and distensibility among 147 HIV-infected patients on ART. CAC scoring was performed with computed tomography. T-tests and Spearman correlations were used to examine the relationships between carotid distensibility and biomarkers of inflammation and immune activation among those with and without detectable CAC.

**Results:** Median (interquartile range) age was 46 (40-53) years; 78% were male and 68% African American. Median CD4 count was 613 (425, 853) cells/μl and 10-year Framingham risk score was 3 (1-7)%. Ninety-three subjects (63%) had zero CAC, but 29 (31%) of those with zero CAC had carotid atherosclerosis by ultrasound (CCA-IMT>1mm or discreet carotid plaque). Median carotid distensibility was higher among those without CAC [26 (19-33) vs. 23 (19-26) 10^-6 Newtons^-1 m^2, p = 0.045, CAC = 0 vs. CAC >0, respectively]; however, 13 subjects (9% of total population) without any CAC or carotid atherosclerosis had carotid distensibility below the 25th percentile. Distensibility was negatively correlated with CD4+ CD38+ HLA-DR+, CD14dimCD16+ (patrolling) monocytes, and IL-6 concentrations among those with CAC = 0, but not among those with CAC >0 (see Table). Among subjects with CAC = 0, distensibility was significantly or marginally significantly correlated with CCA-IMT (r = 0.339, p < 0.001) and two measures of endothelial function (r = 0.192, p = 0.066 for flow-mediated brachial artery dilation; and r = 0.374, p < 0.001 for hyperemic velocity-time integral).

**Conclusions:** Among HIV-infected patients on ART who do not have coronary artery calcification, impaired carotid distensibility may be a sign of early vascular disease that is associated with immune activation and inflammation.

**Table:** Circulating biomarkers of inflammation and immune activation are more strongly correlated with carotid distensibility among subjects without coronary calcification (CAC=0) compared to those with calcified coronary disease (CAC >0).

**729 Microvascular Disease in Controllers Is Mediated by HIV DNA and Immune Dysfunction**

Hiroyu Hatano1, Yifei Ma2, Rebecca Scherzer1, 3, Yuaner Wu2, Elaine Nitta1, Kara Harvill1, Elizabeth Sinclair1, Michael P. Busch1, 2, Steven G. Deeks1, Priscilla Y. Hsue1

1Medicine, University of California San Francisco, San Francisco, CA, United States, 2Pediatrics, University of California San Francisco, San Francisco, CA, United States, 3San Francisco Veterans Affairs Medical Center, San Francisco, CA, United States, 4Laboratory Medicine, University of California San Francisco, San Francisco, CA, United States, 5Blood Systems Research Institute, San Francisco, CA, United States

**Background:** HIV-infected individuals (“controllers”) who are able to maintain low levels of plasma RNA in the absence of antiretroviral therapy (ART) have stable low-level viremia, elevated T cell activation, and a higher risk of cardiovascular disease (CVD). The mechanisms underlying this increased risk are unknown but may include low-level viral replication leading to chronic inflammation and subsequent endothelial dysfunction.

**Methodology:** We performed an open-label study to compare the impact of ART on endothelial function (as measured by flow-mediated vasodilation of the brachial artery [FMD]) and microvascular function (as measured by hyperemic velocity [HV]) in “elite” controllers (EC, n=4), viremic controllers (VC, n=11), and non-controllers (NC, n=5). Lower levels of FMD and HV have been shown to be predictors of future CVD. All subjects received 24-36 weeks of RGV+TDF/FTC. FMD and HV were measured at weeks 0, 4, 24, and 36. Linear mixed models were used to evaluate changes in FMD and HV.

**Results:** Baseline FMD levels were 6.9±2.0% (EC), 5.3±0.9 (VC), and 6.3±1.7% (NC) (p = 0.18, overall test of difference). There were no statistically significant changes over time in FMD (p = 0.24), and FMD did not differ significantly between groups (EC vs. NC, p = 0.98; VC vs. NC, p = 0.17). Baseline HV levels were 101.5±31 cm/(EC), 89.8±19.7 cm/(VC), and 67.3±24.2 cm/(NC) (p = 0.14, overall test of difference). Overall, HV was 39.9 cm higher in EC vs.
NC (p=0.018) and somewhat higher in VC vs. NC (+20.0cm, p=0.13). Both proviral DNA and %CD8+PD1+ levels were significantly lower in EC patients compared to NC at weeks 0, 4, 24; models which controlled for these factors attenuated the differences in HV between EC and NC.

**Conclusions:** In this small pilot study, while 24 weeks of ART resulted in significant reductions in levels of ultrasensitive plasma RNA and T cell activation in HIV-infected controllers, this did not translate into improved macrovascular function (as measured by FMD). However, controllers as a group had better microvascular function (as measured by HV) compared to non-controllers; lower proviral DNA levels and lower markers of immune dysfunction in controllers appeared to mediate the differences in HV. Thus, HIV persistence and immune dysfunction may preferentially impact the microvasculature (rather than the macrovasculature), which may contribute to increased CVD risk. These findings should be replicated in future larger studies that also account for differences between the groups in traditional CVD risk factors.

---

**730 Monocyte But Not Cellular Activation Is Associated With Coronary Atherosclerosis in the MACS**

**Eric S. Daar**, Wendy S. Post, Annie T. Darilay, Peter W. Hunt, Todd T. Brown, Rebeccah McKibben, Beth Jamieson, Mathew J. Budoff, Mallory D. Witt

1Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, United States, 2Johns Hopkins University, Baltimore, MD, United States, 3University of California, San Francisco, San Francisco, CA, United States, 4David Geffen School of Medicine at UCLA, Los Angeles, CA, United States

**Background:** Immune activation is a proposed mechanism for increased cardiac risk in HIV infection. We hypothesize that virally suppressed HIV-infected patients have higher CD8+ T cell and monocyte activation than uninfected controls, and that these measures are associated with coronary atherosclerosis.

**Methodology:** Cross-sectional analyses of HIV-uninfected (n=71) and virally suppressed HIV-infected (n=95) men in Los Angeles, in the Multicenter AIDS Cohort Study (MACS). Non-contrast cardiac computed tomography (CT) for presence of coronary artery calcium (CAC) and CT angiograms for presence of calcified plaque (CP), mixed plaque (MP), non-calcified plaque (NCP) and total plaque (TP) were performed. CD8+ T cell activation (CD38+/HLA-DR+) was assessed by flow cytometry and soluble monocyte activation markers, sCD14 and sCD163 by ELISA. Associations between immune activation and presence of atherosclerosis were assessed with logistic regression, adjusting for age, ethnicity and cardiovascular risk factors.

**Results:** Characteristics, CT and immune marker findings are in Table. HIV-infected men were younger with significantly higher CD8+ T cell activation and plasma sCD14 and sCD163 levels than HIV-uninfected men. There was no evidence for a relationship between CD8+ T cell activation and presence of any type of plaque (P>0.05 for all) in either group. In HIV-uninfected both sCD163 and sCD14 were associated with presence of CAC, adjusted odds ratio [aOR] (95% confidence interval [CI]) 1.82 (1.04, 4.28) and 1.36 (1.01, 2.05), as well as CP, 2.53 (1.37, 6.42) and 1.67 (1.21, 2.67), respectively. For HIV-infected men, sCD14 was not associated with presence of atherosclerosis but sCD163 was for CP, MP and TP with aOR (95% CI) of 1.28 (1.01, 1.66), 1.45 (1.13, 1.91) and 1.56 (1.13, 2.32), respectively.

**Conclusions:** Virally suppressed HIV-infected men had significantly higher CD8+ T cell and monocyte activation than HIV-uninfected men. CD8+ T cell activation was not associated with coronary atherosclerosis in either group. In contrast, the monocyte activation markers sCD14 and sCD163 were associated with coronary calcium and calcified plaque in HIV-uninfected while sCD163 but not sCD14 were associated with presence of calcified, mixed and total plaque in HIV-infected. Further study is needed to define the mechanism behind increased immune activation in virally suppressed HIV-infected patients and the role monocyte activation plays in coronary atherosclerosis.

Alcohol, Smoking, and Atherosclerosis

731 The J-Curve in HIV: Better Cardiovascular-Disease-Free Survival With Moderate Alcohol Intake

Gilles Wandeler1,2, David Kraus1, Jan Fehr3, Anna Conen4, Alexandra Calmy1, Christina Orasch5, Manuel Battegay1, Patrick Schmid4, Enos Bernasconi8, Hansjakob Furrer2

Swiss HIV Cohort Study

1University of Bern, Bern, Switzerland, 2Bern University Hospital, Bern, Switzerland, 3University Hospital Zurich, Zurich, Switzerland, 4Cantonal Hospital St. Gallen, St. Gallen, Switzerland, 5University Hospital Geneva, Geneva, Switzerland, 6University Hospital Lausanne, Lausanne, Switzerland, 7University Hospital Basel, Basel, Switzerland, 8Regional Hospital Lugano, Lugano, Switzerland

Background: In HIV-negative populations light to moderate alcohol consumption is associated with a lower cardiovascular morbidity and mortality than alcohol abstention. Whether the same holds true for HIV-infected individuals has not been evaluated in detail.

Methodology: All adult individuals enrolled in the Swiss HIV Cohort Study who started antiretroviral treatment and had follow-up (fup) time after August 2005 were included. Fup was characterized by alcohol abstention, low (1-9 g/d), moderate (10-29 g/d in females and 10-39g/d in men) and severe alcohol intake. Cox proportional hazards models were used to find an association between alcohol consumption and cardiovascular disease free survival (combined endpoint) as well as cardiovascular disease events (CADE) (myocardial infarction, coronary angioplasty, coronary artery by-pass grafting, carotid endarterectomy, procedures on other arteries, cerebral infarction and cerebral haemorrhage) and overall survival. Baseline and time-updated risk factors for CADE were included in the models.

Results: Among 10,547 individuals included, there were 464 events of CADE and 520 deaths during 52'000 years of fup. The incidence of CADE or death (whichever occurred first) was 1.8 events/100 person-years. Fup according to the alcohol consumption level was 53% abstention, 20% low, 23% moderate and 6% severe intake. As compared to abstention, low (Hazard Ratio (HR) 0.73 (95% Confidence Interval (95% CI) 0.60-0.88; p=0.001)) and moderate alcohol intake (HR 0.67 (0.56-0-80; p<0.001)) were associated with a lower incidence of the combined endpoint, whereas for severe intake no association was detected (HR 0.9 (0.70-1.14; p=0.40)). All classical cardiovascular risk-factors as well as low CD4 cell counts were significantly associated with a higher hazard of CADE or death. The figure shows a fitted curve of daily alcohol consumption level with the HR of the combined endpoint. A similar pattern was observed for overall survival. Alcohol consumption showed a monotonic inverse association with CADE incidence: HR 0.91 (95% CI 0.85-0.97, p= 0.01) per 10g increase of daily alcohol intake.

Conclusions: Compared to abstention, low and moderate alcohol intake is associated with a better CADE free survival in participants of the Swiss HIV Cohort Study on antiretroviral therapy.

732 Soluble CD14 and D-Dimer Are Associated With Smoking and Heavy Alcohol Use in HIV-Infected Adults

Patricia A. Cioe1, Jason Baker2, John Hammer3, Erna M. Kojic4, Nur Onen5, Pragna Patel6, Christopher W. Kahler7

1Center for Alcohol & Addiction Studies, Brown University, Providence, RI, United States, 2University of Minnesota Medical School, Minneapolis, MN, United States, 3Denver Infectious Disease Consultants, Denver, CO, United States, 4Department of Infectious Diseases, Brown University, Providence, RI, United States, 5School of Medicine, Washington University, St. Louis, MO, United States, 6Centers for Disease Control and Prevention, Atlanta, GA, United States, 7Behavioral & Social Sciences, Brown University, Providence, RI, United States

Background: HIV-infected adults are at increased risk for cardiovascular disease (CVD) compared with uninfected adults. In the general population and among HIV-infected adults, biomarkers of monocyte activation (soluble CD14 [sCD14]) and altered coagulation (D-dimer) have been independently associated with increased risk for myocardial infarction, coronary heart disease, and all-cause mortality. We examined whether cigarette smoking and heavy alcohol use were associated with higher levels of these biomarkers in persons living with HIV to inform CVD prevention efforts among HIV-infected persons.

Methodology: The Study to Understand the Natural History of HIV and AIDS in the Era of Effective Therapy (the ‘SUN’ Study) was an observational prospective cohort study that enrolled 700 participants between 2004 and 2006 in four U.S. cities. Biomarkers of monocyte activation (sCD14) and altered coagulation (D-dimer) were analyzed in blood samples from study participants at baseline (n = 689). Each participant completed a baseline audio computer-assisted self-interview to assess behavioral risk factors. Regression analyses examined associations between current cigarette smoking, heavy alcohol use (defined as more than 5 alcohol drinks on at least one day in the past month), and biomarker levels.
Results: Of the 689 participants included in this analysis, 76% were male, 58% non-Hispanic white, 77% were taking antiretroviral therapy, and 73% had an undetectable HIV viral load (<400 copies/mL). Mean age was 41 years and median CD4 count was 438 cells/μL. Heavy alcohol use was reported by 29%, and 42% currently smoked tobacco. In regression analyses, controlling for age, race, current CD4, and viral load, current smoking compared to nonsmoking was associated with significantly elevated sCD14 (B = 135.57, 95% CI (84.95, 186.19), p = .000); whereas heavy alcohol use compared to nondrinking was associated with significantly lower D-dimer levels (B = -0.059, 95% CI (-0.102, -0.016), p = .007).

Conclusions: In this contemporary HIV cohort, current cigarette smoking appears to be associated with elevated sCD14. By contrast, heavy alcohol use is associated with lower D-dimer levels. Smoking cessation should be encouraged by HIV care providers to improve cardiovascular and other all-cause mortality outcomes among HIV-infected persons. However, further research is needed to better understand whether alcohol use confers a protective effect.

733 Antiviral Therapy and Smoking Associated With Coronary Vessel Thickening in HIV-Infected Youth
Aylin Unsal1, Khaled Z. Abd-Elmoniem2, Sarah Eshera3, Julia B. Purdy4, Rohan Hazra1, Colleen Hadigan1, Ahmed M. Gharib2
1National Institute of Allergy and Infectious Disease, National Institutes of Health, Bethesda, MD, United States, 2National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD, United States, 3Critical Care Medicine, National Institutes of Health, Bethesda, MD, United States, 4National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, United States

Background: Individuals infected with HIV early in life may be at higher risk for premature vasculopathy and cardiovascular disease. Whether this increased cardiovascular disease risk is associated with chronic HIV-infection or with long-term antiretroviral therapy has yet to be elucidated. The purpose of this study therefore was to assess subclinical coronary vessel wall thickening and plaque burden in patients infected with HIV early in life compared to healthy controls.

Methodology: This is a prospective cross-sectional study of 35 youth and young adults who acquired HIV in early life and 11 uninfected healthy controls, all free of active cardiovascular disease. Phase-sensitive dual inversion-recovery black-blood vessel wall imaging was utilized for MR imaging of the proximal right coronary artery (RCA) and CT angiography was performed for determination of coronary plaque burden.

Results: HIV-infected subjects (mean age 22; range 15-29 years; 54% male) had significantly increased proximal RCA thickness compared to uninfected controls (mean age 25; 22-29 years; 27% male). RCA thickness in HIV+ was 1.32±0.21 mm vs. 1.09±0.12 mm in controls (p=0.002). HIV status remained a significant predictor of RCA thickness (ρ=0.01), as did smoking pack years (p=0.004), in a multivariate regression adjusting for age, sex, and BMI. The difference in proximal RCA thickness also remained significant in a sub-analysis which excluded HIV+ subjects <20 y (ρ=0.002). Atherosclerotic plaque was present in the coronary vessels among 45% of controls, but only 19% of HIV-infected subjects (ρ=0.1) and plaque was not associated with proximal RCA thickness. There was no association between vessel wall thickness and levels of CRP, d-dimer, pro-BNP, or homocysteine for either study group. Among the HIV-infected subjects, duration of antiretroviral therapy corresponded to vessel wall thickness (ρ=0.38, p=0.02) and duration of stavudine was most closely correlated to RCA thickness (ρ=0.43, p<0.01). These associations remained significant after adjusting for age, BMI and smoking pack years, which also was consistently associated with RCA thickness.

Conclusions: This investigation provides evidence of vascular injury in individuals infected with HIV early in life compared to healthy volunteers, as shown by coronary vessel wall thickness. Among HIV-infected subjects, increased duration of antiretroviral therapy, in particular stavudine, and smoking pack years were strong indicators of proximal RCA thickening. However, coronary vessel wall thickening was independent of atherosclerotic plaque, indicating that vessel wall thickening related to antiretroviral therapy exposure occurs through a mechanism distinct from traditional atherogenesis.

Risk Factors and Incidence: MI and Stroke

734 HIV Infection and the Risk of Cardiovascular Disease in Women
Julie A. Womack1, Chung-Chou H. Chang2, Kaku A. Arnaã1, Kathleen McGinnis1, Matthew B. Goetz1, Cynthia L. Gibert1, Sheldon T. Brown1, Albert L. Warner1, Amy C. Justice1, 2, Matthew S. Freiberg1, 3, 4, for the VACS Project Team
1School of Nursing, Yale University, West Haven, CT, United States, 2University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 3University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA, United States, 4Western Pennsylvania VA Health Care System, Pittsburgh, PA, United States

Background: HIV infection is associated with increased risk of cardiovascular disease (CVD) in women. However, whether HIV is an independent predictor of CVD is unclear. We investigated this question in a cohort of HIV infected (HIV+) and uninfected (HIV-) women.

Methodology: We analyzed data on 2190 women participants (32% HIV+) free of CVD at baseline from the Veterans Aging Cohort Study who were followed from their first clinical encounter (on/after 04/01/2003) until a CVD event, death, or the last follow-up date (12/31/2009). The primary outcome was CVD [acute myocardial infarction (AMI), ischemic stroke, heart failure]. AMI events were defined using clinical data, ICD-9-CM codes and or death certificate data; ischemic stroke and heart failure were determined using ICD-9-CM codes. We used Cox proportional hazards models to assess the association of HIV and incident CVD, adjusting for age, race/ethnicity, lipids, smoking, blood pressure, diabetes, renal disease, obesity, hepatitis C, and substance use/abuse. Using the counting process technique for a time updated Cox proportional hazards model, we explored the risk for CVD among HIV+ women with HIV-RNA levels <500 copies/mL and those with CD4 cell count >200 cells/mm3.
**Results:** During a median follow-up time of 5.9 years, there were 86 CVD events (53%, HIV+): AMI: 24%; ischemic stroke: 20%; heart failure: 56%. Incident CVD/1000 person years was significantly higher among HIV+ (13.5, 95% CI 10.1, 18.1) than HIV- women (5.3, 95% CI 3.9, 7.2, p<0.001), despite the fact that the baseline Framingham risk score was 3 for both groups (p=0.28). After adjusting for all covariates, HIV+ women had an increased risk of CVD compared to HIV- (HR 3.12, 95% CI=1.89, 5.11). Median age at and time to CVD event for HIV+ vs. HIV- women was 49.3 vs. 52.0 years (P=0.05), respectively, and 5.65 vs 6.05 years (p<0.001). In time updated analyses, HIV+ women with HIV-1 RNA levels ≥500 copies/mL (HR=3.23, 95% CI=1.61, 6.47) and <500 copies/mL (HR=3.27, 95% CI=1.82, 5.88) were both at greater risk of CVD compared to HIV- women. There was no difference in risk between the two HIV groups (p=0.97). Similar associations were found for HIV+ women with CD4 cell counts <200 cells/mm³ (HR=2.75, 95% CI=1.54, 4.92) and those with CD4 cell counts ≥200 cells/mm³ (HR=5.63, 95% CI=2.71, 11.7) compared to HIV- women. However the risk of CVD was greater among those with CD4 cell counts ≥200 cells/mm³ (HR=2.02, 95% CI=1.08-4.01, p=0.047).

**Conclusions:** HIV is an independent predictor of CVD in women. These results have important policy and clinical implications given the growing number of HIV+ women and the fact that heart disease is the leading cause of death among women in the US. Research must explore the etiology and predictors of CVD in this high risk population of women.

---

**735 Depression Predicts Incident Myocardial Infarction in HIV+ Veterans: Veterans Aging Cohort Study**

**Tasneem Khabbatty**, Jesse C. Stewart, Samir K. Gupta, Ching-Chou H. Chang, Adee A. Butt, Cynthia L. Gilbert, Hillary A. Tindle, Heidi Crane, Roger Bedimo, Matthew S. Freiberg, on behalf of the VACS project team

1Psychology, Indiana University-Purdue University Indianapolis (IUPUI), Indianapolis, IN, United States, 2Infectious Diseases, Indiana University School of Medicine, Indianapolis, IN, United States, 3University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, 4George Washington University School of Medicine, Washington, DC, United States, 5University of Washington School of Medicine, Seattle, WA, United States, 6Medicine, VA North Texas Healthcare System, Dallas, TX, United States

**Background:** Incidence of acute myocardial infarction (AMI) is higher in HIV-infected patients than in uninfected patients. As depressive disorders are independent risk factors for AMI in the general population, and because depressive disorders are highly prevalent in those with HIV infection, we examined the relationships between these psychiatric conditions and incident AMI in a large sample of HIV-infected patients.

**Methodology:** Our sample included 27,362 HIV-infected men (mean (SD) age: 49 (10) years, 47% African American) from the Veterans Aging Cohort Study Virtual Cohort who were free of cardiovascular disease at baseline (1998-2003). Patients with a diagnosis of either major depressive disorder (MDD; ICD-9 codes 296.2 or 296.3) or dysthymic disorder (ICD-9 code 300.4) during the baseline period were identified as depression cases. Incident AMI was defined as discharge summary documentation and enzyme/ECG evidence of AMI (Veteran Affairs data), an inpatient ICD-9 code 410 (Medicare data), or AMI (ICD-10 code 121) as underlying cause of death (death certificate data) during the follow-up period. All patients were followed for a median of 5.9 years from their first clinic visit on or after April 1, 2003 to an AMI event, death, or the last follow-up date (December 31, 2009).

**Results:** 5,204 (19%) MDD cases and 2,480 (9%) dysthymic disorder cases were identified during baseline, and 363 (1.3%) incident AMI cases occurred during follow-up. Cox proportional hazards models, adjusted for demographics (age, race/ethnicity) and cardiovascular risk factors (hypercholesterolemia, hypertension, smoking, diabetes, body mass index) revealed that any depressive disorder (MDD or dysthymic disorder; HR=1.35, 95% CI: 1.07-1.70 p=.01) was a predictor of incident AMI, as were MDD (HR=1.30, 95% CI: 1.01-1.67 p=.03) and dysthymic disorder (HR=1.50, 95% CI: 1.12-2.03 p=.01) separately. After further adjustment for HIV-related factors (hepatitis C infection, renal disease, alcohol and cocaine abuse, hemoglobin level, CD4 cell count, HIV-1 RNA level, antiretroviral medications), any depressive disorder (HR=1.31, 95% CI: 1.03-1.67 p=.03) and dysthymic disorder (OR=1.47, 95% CI: 1.08-2.01, p=.01) remained predictive of incident AMI, while the HR for MDD (HR=1.28, 95% CI: 0.99-1.65, p=.06) fell just short of significance.

**Conclusions:** To our knowledge, this study is the first to examine depression as a predictor of AMI in HIV-infected patients. Like the general population, our results suggest that depressive disorders are independent risk factors for AMI in this population, and support further research to evaluate whether delivering evidence-based depression treatment may be a novel approach to managing the excess cardiovascular risk of HIV-infected patients with depression.

---

**736 HIV Infection, Cardiovascular Risk Factor Profile, and Risk for Acute Myocardial Infarction**

**Anne-Lise Paisible**, Joyce Chang, Kaku Armah, Matthew B. Goetz, Adee A. Butt, Maria C. Rodriguez-Barradas, David Rimland, Sheldon T. Brown, Amy C. Justice, Matthew S. Freiberg, the VACS Project Team

DeBakey Veterans Affairs Medical Center, Houston, TX, United States, 8Medicine, Baylor College of Medicine, Houston, TX, United States, 9Division of Infectious Diseases, VA Medical Center, Atlanta, GA, United States, 10Emory University School of Medicine, Atlanta, GA, United States, 11James J. Peters Veterans Affairs Medical Center, Bronx, NY, United States, 12Mount Sinai School of Medicine, New York, NY, United States, 13VA Connecticut Healthcare System, West Haven, CT, United States, 14Yale University School of Medicine and Public Health, New Haven, CT, United States

**Background:** Optimal cardiac health is associated with low rates of cardiovascular disease (CVD) though its prevalence is low in the general population. HIV is also associated with acute myocardial infarction (AMI) but the prevalence of optimal cardiac health in this population is unknown. We compared the prevalence of optimal cardiac health by HIV status and assessed whether the association between HIV status and AMI persisted among those with optimal and non-optimal CVD risk factors (CVDRFs) as defined by prior work.

**Methodology:** We analyzed data on 81322 (33% HIV+) who were free of baseline CVD from the Veterans Aging Cohort Study Virtual Cohort, a prospective study of HIV+ and matched HIV- veterans in care. Veterans were followed from their first clinical encounter on or after 4/1/2003 until an AMI event, death or the last follow up date (12/31/2009). We used CVDRFs (total cholesterol, cholesterol lowering agents, blood pressure (BP), BP medication, smoking, diabetes) to create 6 CVDRF profiles: all CVDRFs optimal, 1+ non-optimal CVDRFs, 1+ elevated CVDRFs, and 1, 2, or 3+ major CVDRFs. Incident AMI...
was defined using enzyme and EKG clinical data, an inpatient ICD-9 code 410 in Medicare data, and or death certificate data. We calculated AMI rates and estimated AMI risk using Cox proportional hazard models adjusted for demographics, hepatitis C, renal disease, obesity, and substance use.

Results: During a median of 5.9 years there were 858 AMI events (42% HIV+). The prevalence of optimal cardiac health was <2% for HIV+ and HIV-veterans. Optimal CVDRF profile was associated with lower adjusted AMI rates (Fig 1). Compared to HIV- veterans with the same CVDRF profile, HIV+ veterans had higher adjusted AMI rates, particularly among those with at least 1 major CVDRF present (Fig 1). Adjusted AMI rates among HIV+ veterans increased more with each additional major CVDRF compared to rate increases among HIV- veterans (Fig 1). Compared to HIV-veterans without major CVDRFs, HIV+ veterans without major CVDRFs had a 2-fold increased risk of AMI (HR: 2.0 95%CI: 1.0-3.9, p=0.044) even after covariate adjustment.

Conclusions: The prevalence of optimal cardiac health is low in the VACS VC. Increasing risk factor burden is associated with an increase in AMI rates. This increase is accelerated among HIV+ veterans. Among those without major CVDRFs, HIV+ veterans have twice the AMI risk compared to HIV- veterans. Preventing or reducing CVDRF burden may result in a substantial reduction in AMI risk among HIV+ people.

737 No Difference in Incidence of Myocardial Infarction for HIV+ and HIV- Individuals in Recent Years

Daniel B. Klein1, Wendy A. Leyden1, Chun R. Chao2, Michael A. Horberg3, William J. Towner4, Leo B. Hurley2, Charles P. Quesenberry2, Michael J. Silverberg2

1Kaiser Permanente Northern California, Hayward, CA, United States, 2Kaiser Permanente Northern California, Oakland, CA, United States, 3Kaiser Permanente Southern California, Pasadena, CA, United States, 4Kaiser Permanente Mid-Atlantic States, Rockville, MD, United States, 5Kaiser Permanente Southern California, Los Angeles, CA, United States

Background: With an aging HIV+ population, medical care has increasingly focused on non-AIDS complications such as myocardial infarctions (MI). Here, we compared MI incidence rates between HIV+ and HIV- individuals over time to determine if efforts to reduce MI risk have been successful.

Methodology: We conducted a cohort study from 1996-2011 of HIV+ and 10:1 demographically-matched HIV- Kaiser Permanente California health plan members. Rate ratios (RR) were obtained from Poisson regression models comparing MI incidence rates by HIV status stratified by calendar era (1996-99, 2000-03, 2004-07, 2008-09, 2010-11). Models adjusted for age, sex, race/ethnicity, census-based socioeconomic status, smoking, alcohol/drug abuse, overweight/obesity, diabetes, hypertension, and lipid-lowering therapy. For the most recent era (2010-11), we also compared Framingham risk scores and specific components of the Framingham risk score by HIV status.

Results: 24,768 HIV+ and 257,600 HIV- members contributed 122,032 and 1,522,574 person years, respectively. We observed 320 MIs among HIV+ subjects and 2,483 MIs among HIV- subjects. The crude and adjusted MI RRs for HIV status are shown in the Table. By 2010-2011, the MI incidence rates were similar among HIV+ and HIV- patients with a crude RR of 1.2 (95%CI: 0.7-1.6). In adjusted models, the RR for HIV status in 2010-11 was further reduced to 1.0 (95% CI: 0.7-1.4). In 2010-11, calculated Framingham risk scores were slightly lower in HIV+ patients (9.2% HIV+ and 9.6% HIV-; p<0.001), and fewer HIV patients had high total cholesterol (30.0 vs. 39.6%; P<0.001). However, HIV+ patients had a slightly higher prevalence of hypertension (28.5% vs. 26.2%; P<0.001), and were more likely to have ever smoked (49% vs. 35%; p<0.001) and have HDL<40 (39% vs. 26%; p<0.001).

Conclusions: The increased MI risk in HIV+ patients compared with HIV- patients was no longer observed in recent years. The exact reason for this is unclear, but likely a result of a combination of factors such as cardiovascular risk factor reduction, use of more lipid-friendly antiretrovirals, and reduced immunodeficiency.

| Table. Crude and adjusted MI RRs (95% CI) for HIV status over time (HIV- ref) |
|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| Crude           | 2.0 (1.5, 2.8)  | 2.0 (1.6, 2.5)  | 1.5 (1.2, 1.9)  | 1.5 (1.1, 2.0)  | 1.2 (0.9, 1.6)  |
| Adjusted        | 1.8 (1.3, 2.6)  | 1.7 (1.4, 2.1)  | 1.3 (1.0, 1.6)  | 1.3 (0.9, 1.7)  | 1.0 (0.7, 1.4)  |
MACE Incidence Among HIV- and Non-HIV-Infected Patients in a Clinical Care Cohort

Virginia A. Triant, Susan Regan, Steven Grinspoon
Massachusetts General Hospital, Boston, MA, United States

Background: HIV-infected patients have an elevated risk of coronary heart disease, yet rates of major adverse cardiac events as frequently studied in large clinical trials in the general population remain incompletely characterized.

Methodology: Incidence rates of a composite cardiovascular endpoint were calculated using the Partners HealthCare System HIV longitudinal cohort. The cohort was derived from the Research Patient Data Registry, a clinical care data registry which includes comprehensive clinical information for over 4.5 million patients from the Partners HealthCare System, including Massachusetts General Hospital, Brigham and Women’s Hospital, and their associated outpatient systems. Control patients were matched on the basis of demographic factors. The observation period was between 2000 and 2009, with all patients age 40 or greater at the start of observation. The composite CVD endpoint was ascertained as documentation of relevant ICD-9-CM or CPT codes for myocardial infarction, stroke, angina or coronary revascularization.

Results: The cohort consisted of 3,109 HIV-infected and 23,237 non-HIV-infected control patients followed for 4.8 years (14,942 person-years, PYs) for HIV-infected and 4.6 years (106,885 PYs) for non-HIV-infected patients. Rates of the composite endpoint were 20.8 events (95% confidence interval, CI 18.6-23.3) per 1000 PYs for the HIV-infected patients versus 15.1 (95% CI 14.4-15.9) per 1000 PYs for non-HIV-infected patients. Of the 332 events observed in the infected cohort, 165 (50%) were MI, 124 (37%) were stroke, 35 (11%) were angina and 8 (2%) were revascularization, translating into rates as shown in the Table. Incidence rate ratios (IRR) comparing HIV-infected to non-HIV-infected patients were 1.4 for the overall endpoint, 1.4 for myocardial infarction, 1.3 for stroke, 1.6 for angina, and 1.8 for revascularization.

Conclusions: In a clinical care cohort of HIV-infected and matched control patients, major adverse cardiac events including myocardial infarction, stroke, angina and coronary revascularization were more common among HIV-infected patients when compared as a composite endpoint or individually. The association of HIV with broader CVD endpoints and complications underscores the need for targeted interventions to prevent CVD, particularly in the setting of an aging HIV population.

Lower CD4 Count and Higher Viral Load Are Associated With Increased Risk of Myocardial Infarction

University of Washington, Seattle, WA, United States
University of Alabama at Birmingham, Birmingham, AL, United States
University of California, San Diego, San Diego, CA, United States
Johns Hopkins University, Baltimore, MD, United States
University of North Carolina, Chapel Hill, NC, United States
University of California, San Francisco, San Francisco, CA, United States

Background: There is increasing evidence that cardiovascular disease (CVD) is more common among persons living with HIV (PLWH) than among HIV-negative individuals. However, most previous studies have been limited by small sample size, lack of well-defined clinical events, incomplete case ascertainment, and the use of composite endpoints. We examined which traditional CVD risk factors and HIV-specific factors predict myocardial infarction (MI) in PLWH.

Methodology: CNICS is a multi-center cohort comprised of 8 clinical sites contributing comprehensive clinical data on >27,000 HIV patients followed during routine care. We developed a state-of-the-art screening algorithm and central adjudication protocol for the validation of incident MIs. Among 18,115 eligible participants, we found 1360 individuals with potential incident MIs, of which 314 were confirmed as incident MIs. We used logistic regression to estimate risk of MI associated with baseline Framingham risk score (FRS) covariates (total and HDL cholesterol, systolic blood pressure (SBP), age, sex, diabetes, and smoking) and HIV factors (current CD4, HIV viral load, and transmission risk of injection drug use).

Results: In multivariate analysis the Framingham covariates smoking, age, total and HDL cholesterol, and SBP were significant predictors of incident MI. Diabetes and IDU were not significant. After adjusting for traditional CVD risk factors, each 300 cell/mm3 increase in current CD4 count was associated with a 25% decrease in the risk of MI, and higher HIV viral load was associated with a significant increase in MI risk. Median time between last measured CD4 count and end of follow-up due to event or administrative censoring was 84 days (IQR: 30-172 days).

Conclusions: While FRS covariates remain important, HIV-specific factors are also significantly associated with incident MI in PLWH. Higher prevalence of IDU among females likely confounds the effect of male sex. After adjusting for traditional CVD risk factors, the most recent CD4 count and HIV viral load prior to the event were independent predictors of MI incidence. Our findings highlight the importance of early and effective treatment for PLWH and provide additional evidence, based on a rigorously adjudicated clinical endpoint (MI), that immunodeficiency and active viral replication may be associated with the excess CVD risk in PLWH.

#### 740 Long-Term Effects of Nitrite Inhalants On Cardiovascular and Renal Outcomes in the MACS Cohort

**Alex Holman, Anupriya Dutta, Dana Gabuzda**

Dana-Farber Cancer Institute, Boston, MA, United States

**Background:** Drug abuse is strongly associated with risk behaviors linked to the HIV epidemic, and some forms of drug abuse are associated with more rapid disease progression and increased medical comorbidities. Stimulants, marijuana, and nitrite inhalants are recreational drugs frequently used in HIV-infected populations, but long-term effects of heavy use of these drugs on comorbidities and adverse outcomes with aging are not well characterized.

**Methodology:** Participants were 3366 HIV-negative and HIV-positive gay and bisexual men (68% Caucasian, 21% African American; median age 42 years at baseline visit, median 10 visits per subject) followed at semi-annual visits from 1996-2007 in the longitudinal Multicenter AIDS Cohort Study (MACS). Demographic, clinical, and behavioral variables from the MACS public dataset (p20 release) were translated from the data matrix to create a local SQL database. Substance abuse variables characterizing use of nitrite inhalants (poppers), cocaine, MDMA/MDA, uppers, marijuana, and heroin/opiates were harmonized and synthesized across study visits to classify within-subject trajectories of alcohol, smoking, and drug usage defined by maximum usage reported at 2 or more visits. Unadjusted analyses comparing frequency of cardiovascular diagnoses, eGFR<60 at 2 or more visits, malignancy outcomes, HCV and HBV status, and death outcomes across all study visits in groups classified by HIV status and drug use were performed using Fisher’s exact test (p<0.05).

**Results:** In HIV-negative and HIV-positive subjects (n=1670 and 1589, respectively, 107 seroconverters; >30,000 person-visits), nitrite inhalants (53%), marijuana (44%), cocaine/crack (20%), uppers (10%), and MDMA/MDA (7%) were drugs used most commonly within the prior 6 months. Trajectory analysis showed most subjects had relatively consistent patterns of drug use over the study interval. Frequency of reported popper usage at all levels (daily, weekly, monthly, less than monthly, none) was similar among HIV-negative (3%, 18%, 10%, 19%, 51%) and HIV-positive subjects (3%, 22%, 13%, 19%, 44%). Unadjusted analysis of groups classified by HIV status and heavy (daily/weekly) or episodic (monthly or less) drug use revealed expected associations between cocaine or heroin use and HCV infection regardless of HIV status, and unexpected associations between heavy use of nitrite inhalants and increased frequency of cardiovascular, renal, and malignancy comorbidities in both HIV-negative (p<0.001, 0.02, and 0.004) and HIV-positive subjects (p=0.04, 0.048, <0.001), with median age for these outcomes > age 55.

**Conclusions:** These results suggest long-term adverse effects of heavy nitrite inhalant use on cardiovascular and renal comorbidities in HIV-negative and HIV-positive men.

#### 741 HIV Infection and Immunodeficiency as Risk Factors for Ischemic Stroke

Kaiser Permanente Northern California, Oakland, CA, United States; Kaiser Permanente Southern California, Pasadena, CA, United States; University of California San Francisco, San Francisco, CA, United States; Kaiser Permanente Mid-Atlantic States, Rockville, MD, United States; Kaiser Permanente Northern California, Hayward, CA, United States; Kaiser Permanente Southern California, Los Angeles, CA, United States

**Background:** Large-scale epidemiologic data comparing ischemic stroke between HIV-positive and HIV-negative individuals are limited. We aimed to determine the association of HIV infection and immunodeficiency with ischemic stroke in a large cohort of HIV-positive and HIV-negative individuals with access to care.

**Methodology:** We conducted a cohort study of HIV-positive and demographically-matched HIV-negative members of Kaiser Permanente (KP) California during 1996-2011. Primary diagnoses of acute ischemic stroke were identified using ICD-9 codes 433.x1, 434 (excluding 434.x0), or 436; patients with a prior stroke within two years were excluded. We used Poisson regression to estimate rate ratios (RR) comparing stroke incidence rates between HIV-negative and HIV-positive subjects, both overall and stratified by recent CD4 cells/μL, recent HIV RNA copies/mL, and nadir CD4 cells/μL. Models were adjusted for age, sex, calendar year, race/ethnicity, socioeconomic status, smoking, alcohol/drug abuse, obesity, diabetes, hypertension, and lipid-lowering therapy. We also assessed risk factors for stroke in the HIV-positive subset.
Results: Among 24,768 HIV-positive and 257,600 HIV-negative subjects, the crude stroke incidence rate per 100,000 person-years was 125 for HIV-positive subjects and 74 for HIV-negative subjects, with an adjusted RR of 1.4 (95% confidence interval [CI]: 1.2-1.7). Compared with HIV-negative subjects, HIV-positive subjects with recent CD4 ≥ 500/μL or recent HIV RNA < 500/mL were not at increased risk of stroke (Table). However, compared with HIV-negative subjects, stroke incidence was increased in HIV-positive subjects with recent CD4 < 500/μL and recent HIV RNA ≥ 500/mL, with a weaker association for nadir CD4 < 200/μL (Table). Among HIV-positive subjects, the only HIV-specific risk factor for stroke was recent CD4 < 200/μL compared with ≥ 500/μL (RR 2.5, 95% CI: 1.3-4.6), whereas nadir CD4, recent viral load, and ever having used combination antiretroviral therapy were not independently associated with stroke.

Conclusions: Incidence of ischemic stroke in HIV-positive individuals with recent CD4 ≥ 500/μL was similar to that of HIV-negative individuals, while those with lower recent CD4 were at increased risk. The weaker results for nadir CD4 compared with recent CD4 suggest an acute effect of immunodeficiency on ischemic stroke incidence.

Antiretroviral Therapy, Lipids, and CVD

742 Antiretroviral Therapy Is Associated With Significant Changes in Plasma Lipidome

Janine M. Trevillyan1,2, Gerard Wong3, Rebekah Puls4, Kathy Petoumeno5, Sean Emery6, Natalie Mellett7, Peter J. Meikle3, Jennifer F. Hoy1,2
1Infectious Diseases, Alfred Health, Melbourne, Australia, 2Department of Infectious Diseases, Monash University, Melbourne, Australia, 3Metabolomics, Baker IDI Heart and Diabetes Institute, Melbourne, Australia, 4The Kirby Institute, Sydney, Australia

Background: Targeted measurement of over 400 plasma lipid species by mass spectrometry can sensitively identify changes in the plasma lipidome associated with the development of atherosclerosis and stratify patients into levels of future cardiovascular risk. Some of the HIV and ART-associated cardiovascular risk that persists despite correction for fasting lipids may be explained by changes in plasma lipidome. This study was performed to determine the change in lipidome associated with initiation of different antiretroviral regimens.

Methodology: Plasma lipid profiling (by liquid chromatography, electrospray ionisation-tandem mass spectrometry) was performed on 297 samples from the ALTAIR study which randomised ART-naïve HIV positive participants to one of three initial regimens, enfuvirtide/emtricitabine with efavirenz (EFV), ritonavir-boosted atazanavir (ATZr) or zidovudine/abacavir (ZDV/ABC). Participants (n = 99) who remained on the randomised regimen with complete samples available at baseline, week 12 and 48 were included. 306 lipid species were detected in significant abundance for inclusion.

Results: Baseline characteristics and lipid profile (including lipid classes and species) were similar between the arms. Lower total and LDL cholesterol was seen with ZDV/ABC at week 48 compared with EFV or ATZr. In the EFV and ATZr arms there were significant changes in a number of lipid species from baseline to week 48 (27 and 49 respectively), some of which (4 and 6 respectively) have been previously identified to be associated with cardiovascular events in HIV.

There were no significant changes from baseline seen with ZDV/ABC. At week 48 significant differences in lipid species and classes by treatment regimen were detected; including increased trihexosylceramide (1.24 nM vs 1.0 nM, p < 0.001), monohexosylceramide (9.81 nM vs 6.80 nM, p<0.001) and GM3 ganglioside (4.43 nM vs 3.20 nM, p<0.001) classes with EFV compared with ATZr. The same pattern of results was seen when comparing EFV with ZDV/ABC. The total and percent change in lipid species from baseline to week 48 was not statistically different between arms. Baseline HIV and metabolic characteristics did not predict changes in lipid species. Early change in HIV viral load was predictive of change in 24 lipid species and 1 class at 12 weeks; independent of treatment arm.

Conclusions: ART with EFV or ATVr induces significant changes in plasma lipidome which may be associated with future cardiovascular risk.

743 Rosuvastatin Lowers Cystatin C in HIV-Infected Subjects On Antiretroviral Therapy: SATURN-HIV

Chris T. Longenecker1,2, Corri Lynn O. Hillman3, Norma J. Storer1,2, Dani E. Labatto1,2, Grace A. McConsey1,2
1Case Western Reserve University, Cleveland, OH, United States, 2University Hospitals Case Medical Center, Cleveland, OH, United States, 3MetroHealth Medical Center, Cleveland, OH, United States

Background: In chronic HIV-infection, both creatinine and cystatin C (CysC) based estimates of glomerular filtration rate (eGFRc and eGFRcys) are less accurate than combined estimates (eGFRc-cys) when compared to measured GFR; however, eGFRcys is a better predictor of mortality. This may be explained by non-GFR determinants of plasma cystatin C levels, particularly inflammation. Statins may improve CysC by decreasing inflammation.
Methodology: The Stopping Atherosclerosis and Treating Unhealthy Bone with Rosuvastatin in HIV (SATURN-HIV) trial randomized 147 patients on stable antiretroviral therapy (ART) with LDL-cholesterol <130mg/dL to 10 mg daily rosuvastatin or placebo. We analyzed relationships of baseline and 0-24 week changes in plasma CysC concentration with measures of cardiovascular risk and biomarkers of inflammation and immune activation using Spearman correlation analysis and multiple linear regression.

Results: Median (interquartile range) age was 46 (40-53) years; 78% were male, 68% African American, and 14% had hepatitis C. Tenofovir and protease inhibitors (PI) were used in 88% and 49% of subjects, respectively. Median eGFRcr was 100 (87-118) mL/min per 1.73 m2 and CysC was 0.83 (0.73-0.95) mg/L, without treatment group differences. Baseline CysC concentration correlated with carotid intima-media thickness (r 0.324, p<0.001), carotid distensibility (r 0.193, p=0.019), and coronary calcium score (r 0.170, p=0.040). Baseline CysC was associated with several markers of inflammation and immune activation and with use of PI, but not tenofovir (see Table). Soluble intercellular adhesion molecule-1 (sICAM-1) and tumor necrosis factor-α receptors I and II (TNF-R1/R2) were associated with CysC in a multivariable model independent of eGFRcr. After 24 weeks, mean CysC decreased significantly with statin therapy compared to placebo (-0.034mg/L vs. +0.010mg/L, p=0.008). Within the statin group, changes in CysC correlated with changes in sICAM-1 and TNF-R1 (r 0.460, p<0.001 and r 0.372, p=0.002, respectively).

Conclusions: Rosuvastatin 10mg daily reduces plasma CysC in HIV-infected patients on ART. Baseline CysC concentrations are associated with cardiovascular risk, inflammation and immune activation. Reductions in CysC with statin therapy correlate with reductions in inflammatory biomarkers. The relationship between Cystatin C, cardiovascular disease, and mortality in HIV may partly be related to non-GFR factors such as inflammation.

Table: Relationship of demographics, HIV-specific parameters, and biomarkers of inflammation and immune activation to log-transformed baseline plasma cystatin C concentration.

### 744 Abacavir Induces Leukocyte Accumulation Through the Interaction of ATP and P2X, Receptors

Carmen de Pablo,1,2 Samuel Orden,1 Cesar Ruiz-Navarro,1 María Angeles Martínez-Cuesta,1 Juan V. Esplugues1,3 Angeles Alvarez1,4
1Pharmacology, University of Valencia and CIBERehd, Valencia, Spain, 2Fundación Juan Esplugues, Valencia, Spain, 3FISABIO-Fundación Hospital Universitario Dr. Peset, Valencia, Spain, 4Fundación General Universitat de Valencia, Valencia, Spain

**Background:** The use of abacavir has been linked to cardiovascular disease. We have demonstrated (using a flow chamber system in vitro) that cyclic purine analogues (abacavir and didanosine) induce leukocyte-endothelial cell interactions through Mac-1/ICAM-1 interaction, and that this effect is not produced by pyrimidine analogues (lamivudine, zidovudine, emtricitabine) or the acyclic nucleotide tenofovir. However, the molecular mechanism underlying these interactions remains elusive. Given the chemical structure of abacavir, we have explored whether its proinflammatory effects are a result of the interference of its structure with the purine signalling pathway.

**Methodology:** Human umbilical vein endothelial cells (HUVEC) and polymorphonuclear leukocytes (PMN) were treated with abacavir (0.5-15 μmol/L) to determine: 1) intracellular ATP levels by a luciferase bioluminescence assay; and 2) expression of CD73 (the enzyme responsible for ATP degradation) by western blotting. To analyse the role of ATP and its receptors in the leukocyte accumulation induced by abacavir, HUVEC and PMN were pre-treated with antagonists of P2X, ATP receptors [oxATP (600 μmol/L) or BGG (5 μmol/L)] prior to abacavir (10 μmol/L, 4h) administration and leukocyte-endothelium interactions were then measured using a flow chamber system. Data are expressed as mean±SEM. Statistical analysis was performed with one-way ANOVA and a Newman-Keuls post-hoc test, with significance set at **p<0.01 (vs. control), n≥3.

**Results:** Clinical concentrations of abacavir (0.5-15 μmol/L, 4h) produced an increase in intracellular ATP levels on HUVEC (abacavir 10 μmol/L: 197.6±22.4** vs. 100% control) and PMN (abacavir 10 μmol/L: 158.1±15.4** vs. 100% control) and a decrease in CD73 expression on HUVEC (abacavir 10 μmol/L: 18.7±14.7** vs. 100% control). Abacavir-induced leukocyte-endothelial cell interactions were absent following pre-treatment with P2X, receptor antagonists.

**Conclusions:** Our results suggest a structure-activity relationship in the effects of abacavir on leukocyte accumulation through the interaction of ATP with its P2X, receptors. This proinflammatory mechanism may be especially relevant for understanding the vascular damage observed in abacavir-treated patients.

### 745 LDL Particles and Lipoprotein-Phospholipase A2 A2 in Naive HIV+ Patients Randomized To DRV/r vs ATV/r

Maria Saumoy,1 Jordi Ordóñez-Llano,1 Esteban Martínez,1 Elena Ferrer,1 Gracia Mateo1, Esteban Ribera,1 Eugenia Negro,1 Iñaki Perez1, Daniel Podzamczer1
1Hospital Universitari de Bellvitge, Hospital de Llobregat, Spain, 2Biochemistry Department, Biomedical Research Institute IIB Sant Pau, Barcelona, Spain, 3Hospital Clinic, Barcelona, Spain, 4Hospital de Sant Pau, Barcelona, Spain, 5Hospital Universitari Vall d’Hebron, Barcelona, Spain, 6Fundació Lluita contra la Sida, Hospital Germans Trias i Pujol, Badalona, Spain

**Background:** Atadar study compared plasma lipids in HIV naive patients randomized to Atazanavir/ritonavir (ATV/r) or darunavir/ritonavir (DRV/r) plus tenofovir/emtricitabine (NCT 01274780, 11th HIV Congress, Glasgow 2012, abstract O423). The aim of this substudy was to obtain a more profound knowledge of the proinflammatory properties of lipids changes by the analysis of LDL particles and lipoprotein-phospholipase A2 (Lp-PLA2) A2 at week 48.

**Methodology:** Multicenter, randomized study. Fasting total cholesterol (TC), high density lipoprotein (HDL-c), and low density lipoprotein (LDL-c)-cholesterol, Apo A-I, Apo B, triglycerides (TG), LDL size (by gel electrophoresis) and Lp-PLA2 activity (by 2-thio-PAF) were measured at baseline and w 48. Comparisons between groups and within groups were performed by t-student and paired t test. Multivariate analysis was done by regression analysis. Variables are expressed as mean (SD).

**Results:** Eighty-six (ATZ/r n=45 and DRV/r n=41) patients were included: age 36.7 (8.7), 89% men, 51.1 % current smokers. No differences in demographic and lipid measurements were found at baseline: TC 150.7 (28.7), LDL-c 92.5 (26.1), HDL-c 36.7 (9.9), TG 112.7 (71.5) mg/dL, LDL size 270.6 A(2.95), total Lp-PLA2 22.3 umol/min-1xml (6.31), 34% (10.6) in HDL particles and 66 %(10.6) in LDL particles. At w 48 an increase in TC (+15.5 (41.8); p=0.03 and +14.9 (28.3);p=0.004 in ATZ/r and DRV/r) and HDL-c (+5.4 (8.8); p<0.001 and +3.5 (8.2);p=0.02 in ATZ/r and DRV/r) was observed, with LDL-c increasing only in DRV/r (+10.5 (27.5);p=0.035) and TG in ATZ/r (+39.4 (85.6); p=0.002). Only TG change was significantly different between arms, favoring DRV/r (p=0.02). No change was found in TC/HDL-c while Apo A-I/Apo B increased in ATZ/r (+0.16 (0.4); p=0.02). LDL particles size increased only in DRV/r (+10.5 (27.5);p=0.035) and TG in ATZ/r (+39.4 (85.6); p=0.002). Only TG change was significantly different between arms, favoring DRV/r (p=0.02). No change was found in HDL-c while Apo A-I/Apo B increased in ATZ/r (+0.16 (0.4); p=0.02). LDL particles size increased only in DRV/r (+10.5 (27.5);p=0.02; p (between arms)=0.006), associated with a shift to the less atherogenic LDL phenotype A (80% at baseline to 91.4% at w 48 in DRV/r and 73.3% at baseline to 69.2% at w 48 in ATZ/r arm, p (between arms at w 48)= 0.06). No changes in total Lp-PLA2 activity nor in the distribution in LDL or HDL particles were found at w 48; nevertheless a decrease in HDL-Lp-PLA2 activity was observed in both arms (-0.72 (1.41); p<0.001 in ATZ/r and -0.96 (2.54); p=0.06 in DRV/r). In multivariate analysis, only TG change was related to LDL particle size change (b -0.138 (-0.19 to -0.086); p=0.001).

**Conclusions:** An improvement in the atherogenicity of LDL particles was found in DRV/r arm, related to a lower TG increase. No significant changes in total Lp-PLA2 were observed in any arm, although HDL-Lp-PLA2 decreased with both PI/r-based regimens.

### 746 Darunavir or Atazanavir vs Raltegravir Lipid Changes Are Unlinked To Ritonavir Exposure: ACTG 5257

Ighovwerha Oofotokun1, Heather Ribaud1, Lorraine Na1, Grace McComsey1, Susan E. Cohn1, Catherine Godfrey1, Manish Sagar1, Frances Aweeka1, Jeffrey Lennox1, Judith Currier1
1Department of Medicine, Emory University School of Medicine, Atlanta, GA, United States, 2Harvard University, Boston, MA, United States, 3Case Western University, Cleveland, OH, United States, 4Northwestern University, Chicago, IL, United States, 5National Institute of Allergy and Infectious Diseases, Bethesda, MD, United States, 6University of California San Francisco, San Francisco, CA, United States, 7University of California Los Angeles, Los Angeles, CA, United States

**Background:** Lipid profiles following antiretroviral therapy (ART) vary by regimen type and by ritonavir (RTV) exposure. Changes in fasting lipid profile (FLP) were assessed after ART initiation and correlated with plasma RTV trough concentrations (C24) in the AS257 study.
Methodology: ART-naïve individuals >age 18 years with HIV-1 RNA level >1000 copies/mL were eligible. Subjects were randomized 1:1:1 to ATV (atazanavir 300 mg daily (QD)+RTV 100 mg QD), RAL (raltegravir 400mg twice daily) or DRV (darunavir 800mg QD+RTV); all subjects received emtricitabine/tenofovir 200/300 mg QD. Subjects were followed until the last enrolled reached 96 weeks. FLP was measured at weeks 0, 24, 48, 96, and 144, and steady state RTV C24 (24±2 hours post dose) was measured once for a subset of subjects on RTV tablet. Mean changes in FLP over time from baseline were plotted with 95% confidence intervals (CI), differences between ART regimens were estimated with 97.5% CI and compared using pairwise Student’s T-tests. Associations between RTV C24 and changes in FLP at 48 weeks were evaluated via Spearman correlations.

Results: A total of 1809 subjects were enrolled; 34% non-Hispanic white, 42% non-Hispanic black, 22% Hispanic. 24% were women. Subjects with confirmed baseline fasting samples were included in the analyses (n=1797). Baseline overall median HDL-cholesterol (HDL-C) 38 mg/dL, calculated LDL-cholesterol (LDL-C) 92 mg/dL, and triglycerides (TG) 103 mg/dL. LDL-C and TG levels increased with DRV and ATV but not with RAL from baseline to week 144 (Fig 1a-b). While these 2 lipid parameters were not different between DRV and ATV, each protease inhibitor (PI) arm had greater increases in these parameters compared with the RAL arm (all p≤0.001). HDL-C increased modestly with no differences between arms (all p>0.05) [Fig 1 c]. As-treated and sensitivity analyses excluding subjects on lipid-lowering agents did not change results. RTV C24 was quantified in a subset (109 on ATV and 119 on DRV) with median values of 69 ng/mL and 74 ng/mL in the ATV and DRV arms, respectively (p=0.9). No significant correlation existed between RTV C24 and changes in any of the lipid parameters (p>0.1) (Fig 1d).

Conclusions: The RAL arm produced the most favorable lipid profile. RTV C24 was not different between the 2 PI arms and had no relationship with the modest but similar increases in lipids observed with either the ATV or the DRV arm. The long-term clinical significance of the lipid changes noted in the PI arms relative to the RAL arm are unknown.

Figure 1: Panels a-c: Mean of Changes from Baseline in Fasting Lipid Profile (mg/dL) over Time; panel d: C24 (log(ng/mL)) and Fasting Triglycerides: Change from Baseline to Week 48
747LB Is There Continued Evidence for an Association Between Abacavir and Myocardial Infarction Risk?

Caroline Sabin1, Peter Reiss2, Lene Ryom2, Stephane de Wit3, Ole Kirk3, Rainer Weber2, Christian Pradier4, Matthew Law7, Andrew Phillips1, Jens Lundgren2, DAD Study Group

1UCL, London, United Kingdom, 2Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, 3Copenhagen HIV Programme, University of Copenhagen, Copenhagen, Denmark, 4Department of Infectious Diseases, St Pierre University Hospital, Brussels, Belgium, 5Division of Infectious Diseases, University Hospital Zurich, Zurich, Switzerland, 6Nice Hospital, Nice, France, 7The Kirby Institute, Sydney, Australia

Background: In March 2008, the D:A:D study published results showing an increased risk of myocardial infarction (MI) in those on abacavir (ABC). We describe changes in use of ABC since publication, and reinvestigate this association with subsequent follow-up.

Methodology: D:A:D participants were followed from study entry until the first of: MI, death, 1st Feb 2013 or end of follow up. Associations between 10-year Framingham cardiovascular disease (CVD) risk (low [<10%], moderate [10-20%], high [>20%] or unknown [U/K]) and likelihood of initiating or discontinuing ABC were assessed with multivariable logistic/Poisson regression. Poisson regression also assessed the association between current ABC use (with 6-month lag to allow for recent discontinuation) and MI risk, adjusting for use of other ART drugs and confounders. Analyses were performed separately pre- and post-March 2008.

Results: Use of ABC increased from 10% in 2000 to 20% in 2008, before stabilising at 18-19% (Figure). Increases in use pre-March 2008, and subsequent decreases, were greatest in those at moderate and high CVD risk. Post-March 2008, those on ABC at moderate/high CVD risk were more likely to discontinue ABC than those at low/unknown CVD risk, regardless of VL (<1000 cps/ml: relative rate (RR) 1.49 [95% CI 1.34-1.65]; >1000 cps/ml: 1.23 [1.02-1.48]); no such associations were seen pre-March 2008. There was some evidence that ART-naive people at moderate/high CVD risk post-March 2008 were less likely to initiate ABC than those at low/unknown CVD risk (odds ratio 0.74 [0.48-1.13]). By 1st Feb 2013, 941 MI events occurred in 367,559 person years (PYRS) (rate 0.26 [0.24-0.27]/100 PYRS). Rate of MI was 0.47 [0.42-0.52] for current ABC use and 0.21 [0.19-0.22] otherwise. Current ABC use was associated with a 98% increase in MI rate (RR 1.98 [1.72-2.29]), with no difference in the pre- (1.97 [1.68-2.33]; 672 events, 210,250 PYRS) or post- (1.97 [1.43-2.72]; 269 events, 157,309 PYRS) March 2008 periods (interaction p=0.74). Results were unchanged after further adjusting for factors potentially on the causal pathway (pre-March 2008: 1.88 [1.55-2.28]; post-March 2008: 2.03[1.46-2.84]), including renal function, dyslipidaemia and hypertension.

Conclusions: Despite channelling of ABC away from those at higher CVD risk since 2008, we continue to observe an association between ABC use and MI risk. Whilst confounding cannot be ruled out in any cohort study, this argues against channelling bias as an explanation for our findings.

748 Lipidomic Profiling in HIV: Implications for Risk-Prediction Models

Gerard Wong1, Janine M. Treviliani2,3, Benoit Fatou1, Michelle Cinel1, Jacqui Weir1, Jennifer F. Hoy2,3, Peter J. Meikle1, Peter J. Meikle1

1Metabolomics, Baker IDI Heart and Diabetes Institute, Melbourne, Australia, 2Infectious Diseases Unit, Alfred Health, Melbourne, Australia, 3Department of Infectious Diseases, Monash University, Melbourne, Australia

Background: HIV positive patients are at increased risk for coronary artery disease (CAD) with both HIV and antiretroviral associated dyslipidaemia contributing. Targeted analysis of over 400 plasma lipid species by mass spectrometry can sensitively identify changes in the plasma lipidome associated with the development of atherosclerosis.

Methodology: In a retrospective case-control study we profiled the plasma lipidome (268 lipid species included) of 113 subjects. Cases (n=23) were HIV positive individuals who had a blood sample available in the 12 months prior to the diagnosis of CAD. They were age and sex matched 1:2 with HIV positive individuals without a diagnosis of CAD (n=45, HIV+ controls) and with healthy HIV negative volunteers (n=45, Healthy controls). Risk prediction models incorporating the plasma lipidome were compared with established cardiovascular risk scores.

Results: 104 (92%) were male with a median age of 52.2 years (IQR 40.9-61.4). HIV patients (combined cases and HIV+ controls) were more likely to smoke (31 [45.5%] vs 3 [6.7%], p <0.001), had higher median hsCRP (2.78 [IQR 1.97 - 6.67] vs 0.64 [IQR 0.36 - 1.48], p<0.001) and triglyceride levels (1.77 [IQR 1.47-2.76] vs 1.00 [0.7-1.76], p <0.001) and lower high density lipoprotein cholesterol (0.95 [IQR 0.78 - 1.13] vs 1.50 [IQR 1.1 - 1.7], p <0.001) than healthy controls. 23 (100%) of cases and 40 (88.9%) of HIV+ controls were currently receiving antiretroviral therapy. 83 lipid species and 7 lipid classes were identified that were significantly associated with HIV infection. A further 74 species and 8 classes where significantly associated with future CAD event. 15 species (predominantly in the triacylglycerol and diacylglycerol classes) were elevated in HIV infection and further elevated in HIV positive patients are at increased risk for CAD. Risk prediction models incorporating lipid species outperformed (AUC=0.78 (0.775,0.785)) all other tested risk scores (including the Framingham, Reynolds and the Data Collection on Adverse Events of Anti-HIV drugs [D:A:D] risk equations) in the identification of HIV positive subjects who went on to develop CAD.
Conclusions: Treatment-experienced HIV positive patients demonstrate significant differences in plasma lipidome when compared with healthy HIV negative controls. There is a potential application for improved cardiovascular risk screening of HIV positive patients in the clinical setting by including lipid species in risk prediction models.

749LB Effect of Switch From Abacavir To Tenofovir DF On Platelet Function Markers: A SWIFT Trial Substudy
Jane A. O’Halloran1, Eimear Dunne2, Willard Tiongo1, Stephanie Denieffe1, Dermot Kenny2, Patrick W. G. Mallon1
1HIV Molecular Research Group, University College Dublin, Dublin, Ireland, 2Cardiovascular Biology Group, Royal College of Surgeons in Ireland, Dublin, Ireland

Background: Current and recent use of the nucleoside reverse transcriptase inhibitor, abacavir (ABC) has been associated with increased risk of myocardial infarction, with both endothelial dysfunction and altered platelet reactivity with ABC use implicated.

Methodology: Changes in markers of platelet function were examined in a sub-study of the SWIFT trial, a prospective, randomised, 48-week trial of virally suppressed, protease-inhibitor-treated, HIV-1 positive subjects randomised to switch abacavir/ lamivudine (ABC/3TC) to tenofovir disoproxil fumarate/ emtricitabine (TDF/FTC) or remain on ABC/3TC. Soluble glycoprotein VI (sGPVI), a marker of collagen-mediated platelet activation and soluble P-selectin (sP-sel), involved in platelet-leucocyte interactions, were measured by enzyme-linked immunosorbent assays (Meso Scale Discovery, Rockville, MD) in stored plasma samples collected at weeks 0, 4, 12, 24, 36 and 48. Changes in platelet markers over time were assessed using mixed effect models. Data are mean [SD] unless specified.

Results: Of 312 patients (age 46 [9.3] years, 85% male, 65% Caucasian), 156 switched to TDF/FTC. Groups were well matched for baseline demographic and laboratory data including CD4+ T-cell count (TDF/TFC versus ABC/3TC, 548 [257], 582 [287] /μl respectively), platelet count (244 [58], 253 [72] x103/μl), total cholesterol (5.4 [1.2], 5.3 [1.0] mmol/L), LDL (3.1 [1.0], 3.1 [0.8] mmol/L) and HDL (1.29 [0.38], 1.31 [0.42] mmol/L) cholesterol and history of dyslipidaemia or hypertension. There were no between-group differences in baseline sGPVI (mean (SEM) 3.75 [0.25] ng/ml versus 3.61 [0.22] ng/ml, p=0.68) or sP-sel (65.0 [2.2] ng/ml versus 69.2 [2.9], p=0.25) and no between-group differences in change in sP-sel from baseline to 48 weeks (p=0.37, figure 1b). However, relative to the ABC/3TC group, sGPVI increased to week 48 in those who switched to TDF/FTC (effect size +0.012 (95%CI 0.0041, 0.02), between group p=0.002, figure 1a). This effect persisted when corrected for age, ethnicity, history of dyslipidaemia or hypertension, baseline CD4+ T-cell and platelet count and change from baseline to week 48 in creatinine, LDL, HDL, CD4+ T-cell and platelet count.

Conclusions: The observed increases in sGPVI point to changes in intrinsic platelet function with a switch away from ABC/3TC to TDF/FTC. Further mechanistic research is required to determine the relevance of these changes on overall platelet reactivity and cardiovascular disease.

Figure 1. Change in markers of platelet function over time

750 Rosuvastatin Lowers Oxidative LDL in HIV-Infected Persons On Antiretroviral Therapy: SATURN-HIV
Corrilynn O. Hileman1, 2, Richard D. Semba3, Randi Turner4, Danielle E. Labbato1, 4, Norma J. Storer1, 4, Grace A. McComsey1, 4
1Case Western Reserve University School of Medicine, Cleveland, OH, United States, 2MetroHealth Medical Center, Cleveland, OH, United States, 3Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 4University Hospitals Case Medical Center, Cleveland, OH, United States

Background: Circulating oxidative low density lipoprotein (oxLDL), a known risk marker for cardiovascular disease (CVD), has not been well studied in HIV. Also, in HIV-uninfected populations, statins reduce oxLDL, but their effect in HIV is unknown. We report the first comprehensive study of oxLDL in HIV assessing its relationship to immune activation and CVD risk, and changes in oxLDL with rosuvastatin.

Methodology: We randomized 147 patients on stable antiretroviral therapy with LDL ≤130mg/dl to rosuvastatin 10 mg daily or placebo. Baseline and 0-24 week changes in oxLDL and oxLDL:LDL ratio were compared between groups. Spearman correlation was used to explore relationships between baseline oxLDL and oxLDL:LDL with inflammation/immune activation markers and CVD risk measures. Linear regression was used to determine predictors of 0-24 week change in oxLDL and oxLDL:LDL in the rosuvastatin group.
**Results:** Overall, 78% were men, 68% African American, 63% current smokers, 49% were on a protease inhibitor. Baseline median (Q1-Q3) age was 46 (40-53) years, BMI 27 (23-30) kg/m², CD4+ count 613 (425-853) cells/mm³ and 79% had HIV-1 RNA ≤50 copies/mL. Baseline LDL was 97 (77-113) mg/dL, OxLDL 45 (37-56) U/l and OxLDL:LDL 18 (15-23) U/mmol without differences between groups. The table shows correlates of OxLDL and OxLDL:LDL at baseline. OxLDL was significantly correlated with HOMA-IR ($\rho$ = 0.17; p = 0.038), hyperemic velocity (measure of microvascular health) ($\rho$ = 0.16; p = 0.051) and carotid distensibility (measure of vascular stiffness) ($\rho$ = 0.17; p = 0.047), but not with brachial artery flow mediated dilation, carotid intima media thickness or coronary artery calcification. After 24 weeks OxLDL decreased significantly within the rosuvastatin group (p<0.0001) and vs placebo (-6.4% vs +1.02 U/l; p<0.01); whereas OxLDL:LDL increased with rosuvastatin (p<0.01) and vs placebo (+3.25 vs -0.5 U/mmol; p = 0.02). CD4+ count ($\beta$ = -3.58x10^-6; p = 0.047), cystatin C ($\beta$ = -0.75; p = 0.003), change in LDL ($\beta$ = 0.01; p = 0.025) and change in HDL ($\beta$ = -0.02; p = 0.011) were independently associated with change in oxLDL in the rosuvastatin group, but not change in any inflammation or immune activation markers.

**Conclusions:** In HIV, OxLDL levels are associated with several inflammation markers as well as insulin resistance, microvascular health and vascular stiffness. Rosuvastatin decreased oxLDL over 24 weeks, but this was not associated with changes in inflammation or immune activation.

751LB After 52 Weeks, Pitavastatin Is Superior To Pravastatin for LDL-C Lowering in Patients With HIV

Craig A. Sponseller¹, Judith Aberg², INTREPID Team

¹Medical Affairs, Kowa Pharmaceuticals America, Inc., Montgomery, AL, United States, ²Chief, Division of Infectious Diseases, ICAHN School of Medicine at Mount Sinai, New York, NY, United States

**Background:** Based on current guidelines for patients with HIV and dyslipidemia, statins with the lowest potential for drug-drug interactions (DDIs) with antiretroviral therapy (ART) are recommended. Pitavastatin (PTA) has a reduced potential for cytochrome P450-mediated DDIs and in the phase 4 trial INTREPID, PTA 4 mg demonstrated superior LDL-C reduction vs pravastatin (PRA) 40 mg in adult, HIV subjects after 12 weeks. The objective was to evaluate the safety and secondary efficacy endpoints of PTA 4 mg vs PRA 40 mg following the INTREPID 40-week safety extension (Week 52).

**Methodology:** INTREPID was a 12-week, phase 4, randomized (1:1), double-blind, double-dummy, active-controlled, parallel-group superiority study followed by a 40-week safety extension. Eligible patients (250 planned for enrollment for ~ 90% power to detect difference in LDL-C) were on stable ART as the independent variable, adjusting for site and randomized viral hepatitis B or C infection status. Safety assessments included AEs, clinical/laboratory tests, HIV-1 RNA load, CD4 count, and virologic failure.

**Results:** 252 patients were randomized (126/group): mean age ~ 50 years, BMI ~ 28 kg/m², male ~86%, Caucasian ~80%, and negative for hepatitis B or C infection (90.5%). After 52 weeks, LDL-C reduction was statistically superior for PTA (-30%) vs PRA (-21%) with a treatment difference of -8.4% ($\rho$ = 0.0007)(Table). Increases in HDL-C and decreases in TG were not significantly different between PTA and PRA. Subjects experiencing TEAEs through Week 52 were similar between PTA (85 subjects; 67.5%) and PRA (88 subjects; 69.8%). The frequency of TEAEs leading to study discontinuation was similar between PTA (4.8%) and PRA (4.0%). HIV-1 RNA viral load mean change was 0.03 copies/mL (mean 6.5%) in the PTA group and 0.07 copies/mL (mean 9.2%) in the PRA group. No deaths and no notable changes in CD4 count or AST/ALT for either treatment. Virologic failure occurred in 4 (3.2%) PTA subjects and in 6 (4.8%) PRA subjects.

**Conclusion:** Pitavastatin 4 mg demonstrated sustained safety and was superior to pravastatin 40 mg in LDL-C reduction after 52 weeks of therapy in HIV-infected adults with dyslipidemia.
**Poster Abstracts**

**Methodology:**
HIV-infected persons >50 years of age with plasma HIV-1 RNA <50 copies/mL on stable ART and on EPC number and type in older HIV-infected patients.

Telmisartan is an angiotensin receptor blocker that increases EPC production in HIV-uninfected persons (Pelliccia, 2010); therefore, we assessed its effects (Lucke, 2010). Endothelial dysfunction and decreased EPC numbers have been documented in HIV-infected patients (Teofili 2010; da Silva 2011).

**Background:** Bone marrow-derived endothelial progenitor cell (EPC) production reflects endothelial regenerative capacity. EPC production is partially mediated by angiotensin II, decreases with age, and correlates with measures of vascular function and cardiovascular disease (CVD; Hill, 2003; Schmidt-Lucke, 2010). Endothelial dysfunction and decreased EPC numbers have been documented in HIV-infected patients (Teofili 2010; da Silva 2011). Telmisartan is an angiotensin receptor blocker that increases EPC production in HIV-uninfected persons (Pelliccia, 2010); therefore, we assessed its effects on EPC number and type in older HIV-infected patients.

**Methodology:** HIV-infected persons >50 years of age with plasma HIV-1 RNA <50 copies/mL on stable ART and ≥1 CVD risk factor were recruited and received open label telmisartan 80mg daily for twelve weeks. In this exploratory analysis, EPCs were quantitated via flow cytometry using fresh blood. Using CD34 and CD133 as markers of “early” EPC maturity and KDR as a marker for endothelial lineage commitment, EPCs were defined as viable CD34-/CD33-/CD19- cells that were also CD133+/KDR+, CD34+/KDR+, CD34+/CD133+, or CD34+/KDR+/CD133+.

**Results:**

*One subject excluded for increasing statin dose between weeks 6 and 12
†2 subjects off drug
IQR=Interquartile range
**Poster Abstracts**

**Results:** Seventeen subjects (65% non-Caucasian, 88% male, median age 60 years, Framingham risk score 10%, BMI 27 kg/m2, blood CD4+ T cell count 625 cells/mm3) enrolled and completed all evaluations. Frequencies of ART classes used in this group included: 71% PI, 29% NNRTI, 29% integrase inhibitor, 65% TDF, 29% ABC. Cardiovascular risk factor prevalence in this group included: 82% hyperlipidemia, 65% hypertension, 18% current tobacco use, 12% diabetes mellitus. After twelve weeks, absolute numbers of all EPC subtypes increased significantly (see table), including CD34+/133+/KDR+ EPCs, which are rare in circulation but highly specific for EPC lineage. In a subset analysis of CD34+ EPCs, maturity markers remained stable, but endothelial commitment increased.

**Conclusions:** Telmisartan increased endothelial regenerative potential (EPC number and type) in older HIV-infected patients on ART. The magnitude of EPC increase (specifically CD34+/KDR+ cells) was greater than previously reported amongst HIV-uninfected persons with coronary artery disease (Endtmann, 2011), however the exact clinical significance of this is unknown. Larger, randomized studies are needed to confirm this finding and define telmisartan’s role as an agent for endothelial preservation in HIV-infected patients.

### 753 Incidence of CD4/CD8 Ratio Normalization and Its Role in the Onset of Non-AIDS-Related Events

*Cristina Mussini*1, Patrizia Lorenzini2, Alessandro Cozzi-Leprini1, Giuseppe Lapadula2, Giulia Marchetti3, Emanuele Nicastrì2, Antonella Cingolani2, Miriam Lichtner3, Andrea Antinori1, Antonella d’Arminio Monforte1, for the Icona Foundation Study Group

1University of Modena and Reggio Emilia, Modena, Italy, 2Institute of Hematology, Milan, Italy, 3University College London, London, United Kingdom, 4San Gerardo Hospital, Monza, Italy, 5University of Milan, Milan, Italy, 6Catholic University, Rome, Italy, 7La Sapienza University, Rome, Italy

**Background:** Immune-reconstitution after therapy (cART) is often either quantitatively or qualitatively incomplete. Aim of the study was to evaluate in the Icona cohort patients (pts) the probability of reaching a CD4/CD8 ratio >=1 after starting cART and its possible protective role against the onset of non-AIDS related events (nADE) or death for any cause.

**Methodology:** Pts were included if started cART, reached undetectable viral load (VL) (<=80 copies/mL) (time 0 of the analysis) and had a CD4/CD8 ratio at undetectability 1. nADE were: cardiovascular events, stroke, non-AIDS defining cancers. Multivariable Poisson regression model was used to analyze factors independently associated with normalization and with clinical progression.

**Results:** 3,236 pts were included, 76.4% males, mean age 39 years, 88.3% Italians, 18.3% CDC stage C. At starting cART, mean CD4 was: 223 cells/uL (range 101-317) and mean CD4/CD8 ratio was 0.39 (range 0.26-0.55). 717 pts (22.2%) were HCV co-infected and 178 (5.5%) HBV. Median CD4 count at time 0 was 378 cells/uL (range 249-518). Over 7,305 PYFU, 458 pts reached a CD4/CD8 ratio >1 [IR=6.3 per 100 PYFU (95%CI 5.7-6.9)]. Probability of normalization was 30%, 95%CI 26%-35% by 15 years using KM method. At multivariable analysis, factors associated with a higher chance of achieving normalization were: a higher CD4/CD8 ratio before starting cART (RR: 1.72 for 0.10 higher, 95%CI 1.62-1.83; p=0.000) and having started cART more recently (RR: 1.03 per more recent year, 95%CI 1.01-1.06; p=0.007). In contrast, older pts (RR: 0.87 per 10 year older, 95%CI 0.78-0.97; p=0.016), homosexual contacts (RR: 0.74 vs. heterosexuals; 95%CI 0.57-0.96; p=0.022), those with a nadir CD4 value below 200 (RR: 0.73 vs. >200, 95%CI 0.57-0.95; p=0.017), HBV co-infected (RR 0.58 vs. HIV mono-infected, 95%CI: 0.35-0.99; p=0.045) and those treated with AZT/3TC (RR 0.70 95%CI 0.48-1.00 p=0.051) or ddI/ddT (RR 0.31 95%CI 0.11-0.87 p=0.027) using tdf+ftc as reference were less likely to achieve normalization. CD4/CD8 was associated with the risk of developing nADE or death independently of current CD4 count (Table 1).

**Conclusions:** A minority of pts who start cART reaches a CD4/CD8 ratio >1. Younger patients, those with a higher CD4/CD8 ratio at time of viral suppression and those starting cART more recently and with higher CD4 count have higher possibilities to achieve normalization. The CD4/CD8 ratio was predictive of clinical progression independently from CD4 cell count.

*Adjusted for gender, mode of HIV transmission, white race, and the following variables measured at baseline: age, HCV coinfection, CDC C stage and log10 HIV-RNA. No colinearity problems were found (mean VIF=1.13).
754 Longitudinal Changes in Free Testosterone Among Older HIV-Infected and HIV-Uninfected Men

Laurence Sliwa1, 2, Lisa P. Jacobson3, Xiaohong Li1, Frank J. Palenius2, Joseph B. Margolick4, Lawrence Kingsley5, Dorothy Wiley5, Gilles Pialoux1, Adrian Dobs7, Todd T. Brown1

1Infectious Diseases, Tenon Hospital, Paris, France, 2Infectious Diseases, Northwestern University, Feinberg School of Medicine, Chicago, IL, United States, 3Epidemiology, Johns Hopkins University, Baltimore, MD, United States, 4Infectious Diseases, Johns Hopkins University, Baltimore, MD, United States, 5Infectious Diseases, University of Pittsburgh, Pittsburgh, PA, United States, 6School of Nursing, University of California, Los Angeles, CA, United States, 7Endocrinology, Diabetes, and Metabolism, Johns Hopkins University, Baltimore, MD, United States

Background: In the general population, aging is associated with lower testosterone levels and a decrease in the diurnal variation of testosterone secretion. Although cross-sectional studies have shown lower than expected testosterone levels in HIV-infected men, it is unclear whether age-related longitudinal changes in serum testosterone differ by HIV serostatus.

Methodology: We identified HIV-infected men from the Multicenter AIDS Cohort Study (MACS), age ≥ 45 years at initiation of highly active antiretroviral therapy (HAART), who had ≥ one sample serum available prior to HAART-initiation (i.e. the baseline visit) and ≥ 2 serum samples in the 10 years following HAART-initiation. They were matched to HIV-uninfected men by age, race, MACS site and calendar time of pre and post-HAART samples. Men who received exogenous hormones of any kind and/or had free testosterone concentrations (FT) >150 ng/dL, suggestive of unreported testosterone use, were excluded. Linear mixed effects regression was used to determine whether log FT and its rate of change over the study interval differed by HIV serostatus. Log FT values were back-transformed for reporting.

Results: Data were available from 182 HIV-infected and 267 HIV-uninfected men. The median age at baseline was 48.8 years (Interquartile range (IQR); 45.8, 53.4). The median number of FT measurements per participant was 4 (IQR; 3, 5) drawn over a median of 6 years (IQR; 2.9, 9.5). Of the 1737 samples analyzed, 65% were drawn in the morning. After adjustment for age, race, BMI, hepatitis C status, smoking, the presence of diabetes mellitus and MACS site, median baseline FT levels were significantly lower among HIV-infected men than HIV-uninfected men in morning samples (67 ng/dL [95% Confidence Interval (CI): 65-71] v. 72 ng/dL [95% CI: 69-74], respectively; p=0.037), but not in afternoon/evening samples (65 ng/dL [95% CI:62-69] v. 65 ng/dL [95% CI:62-67], respectively; p= 0.728). However, the annual rate of FT decline after adjustment for time of day of the sample draw and other covariates did not differ significantly by HIV-infected men (95% CI: -0.1% , -1.8%) v. -1.0% for HIV-uninfected men (95% CI: -0.6% , -1.5%), p = 0.913.

Conclusions: FT decreased similarly over a 6-year interval in older HIV-infected and HIV-uninfected men, but FT levels were lower among HIV-infected men, but not afternoon/evening levels. These data may suggest a loss of diurnal variation in FT among HIV-infected men.

755 Inflammatory Biomarkers in Chronic HIV Disease Predominantly Associate With Monocyte Activation

Eleanor M. P. Wilson1, Anmit Singh1, Khathy Huppler Hullsiek2, Keith Henry2, 1, Ken Lichtenstein1, Pragana Patel1, John T. Brooks1, 3, Irini Sereti1, Jason V. Baker2, 3

1Lab of Immunoregulation, NIH, Bethesda, MD, United States, 2University of Minnesota, Minneapolis, MN, United States, 3Hennepin County Medical Center, Minneapolis, MN, United States, 4National Jewish Health, Denver, CO, United States, 5CDC, Atlanta, GA, United States

Background: We have previously shown soluble biomarkers of inflammation, including an IL-6/D-dimer composite score, independently predict non-AIDS related morbidity and mortality. We explored associations between select biomarkers and cellular immunophenotypes to identify potential mechanisms of excess inflammation among HIV-infected adults.

Methodology: Baseline plasma specimens from SUN Study participants were analyzed for levels of IL-6, hsCRP, sCD14, sCD163, and D-dimer. We performed immunophenotyping for markers of T cell activation and maturation (HLA-DR, CD38, CX3CR1, CD28, CD57) and monocyte activation and migration (CCR2, CD14, CD16, tissue factor [TF], CX3CR1, CCR5). We evaluated associations between cellular phenotypes and soluble markers by Spearman rank correlation. Linear regression was used to estimate the percent change in plasma biomarker level for each 5 unit difference in cellular phenotype, after adjustment for: age, gender, race, smoking, diabetes, treatment for hypertension or hyperlipidemia, hepatitis, CD4 cell count, and HIV RNA <400 copies/mL. Due to multiple comparisons, we defined significance as p-value ≤ 0.01.

Results: Participants’ (n=670) median age was 41 years and CD4 count 471 cells/μL; 76% were male, 44% smokers, 88% on ART, and 72% had HIV RNA <400 copies/mL. Correlations of biomarkers with select cellular phenotypes are shown (Table). In fully adjusted models, a 5 unit greater frequency of CD14++CD16+ monocytes was associated with 11.4% higher IL-6 (p<0.001), 27.5% higher D-dimer (p<0.001), and 10.9% higher hsCRP (p=0.004); a corresponding difference of monocytes expressing CCR2 was associated with 6.9% lower D-dimer (p=0.003) and CCR5 with 1.4% higher sCD163 (p<0.001). Of T-cell subsets, greater frequencies of CD4+HLADR+CD38+ T-cells were independently associated with higher sCD163 (5.1%, p<0.001) and CD8+CD8+ T-cells with lower sCD163 (3.0%, p=0.001) and D-dimer (1.2%, p=0.001). Finally, an IL-6/D-dimer clinical risk score was positively associated with CD14++CD16+ monocytes (p<0.001) and inversely with CD8+CD8+ T-cells (p=0.009) in adjusted models.

Conclusions: Plasma biomarkers that strongly predict clinical risk for non-AIDS morbidity were consistently and strongly associated with monocyte activation phenotypes and modestly with T-cell maturation, but not CD8+ T-cell activation, phenotypes. These findings may help direct treatment strategies to control persistent inflammation in chronic HIV disease.

756 Extrinsic Pathway Coagulation Factors Are Associated With Mortality During Treated HIV Disease

Jason V. Baker1, Kathleen Brummel-Ziedins2, Jacqueline Neuhaus3, James D. Neaton4, Russell P. Tracy4, INSIGHT SMART and ESPRIT Study Groups

1Infectious Diseases, University of Minnesota, Minneapolis, MN, United States, 2Biochemistry, University of Vermont, Burlington, VT, United States, 3Biostatistics, University of Minnesota, Minneapolis, MN, United States

Background: We previously reported that HIV replication increases non-hepatocyte dependent procoagulant factors and decreases hepatocyte-dependent pro- and anticoagulant factors, resulting in a procoagulant state. Here we explore mortality risk associated with these changes in the context of treated HIV disease.
Methodology: In a nested case-control study of the SMART and ESPRIT control arms (randomized to continuous antiretroviral therapy), we evaluated all-cause mortality associations with 9 extrinsic pathway factors (listed in Table); 6 are hepatocyte products (FII, FVII, FIX, FX, antithrombin, protein C). Three controls were matched per case on enrollment date, age (+/- 5 yrs), study, and country. Odds ratios (OR) with 95% confidence intervals (CI) for 4th vs. 1st quartile of each marker were estimated using conditional logistic regression accounting for matching factors and adjusting for gender and race. To study the combined effect of the hepatocyte-dependent factors, individual biomarkers for each case/control set were ranked and combined over the 6 biomarkers to obtain a “Hepatocyte Score”. Additional covariates studied included: hepatitis co-infection, diabetes, cardiovascular disease, and baseline CD4, HIV RNA, and IL-6.

Results: Among cases (n=134) and controls (n=388), respectively, median CD4 count was 454 and 495 cells/mm3, and 65 and 77% had viral suppression at baseline. Median factor (F) levels and mortality OR are listed (Table); findings include: 1) mortality increased with higher F and FVII levels (non-hepatocyte procoagulant cofactors), 2) mortality was inversely related to FVII levels, protein C (anticoagulant), as well as the composite hepatocyte score; mortality association for the score was not attenuated after adjustment for all covariates (OR 0.38; p<0.01). 3) When restricted to participants with viral suppression at entry, FV (OR 1.97; p=0.05), FVIII (OR 2.28, p=0.03), FVII (OR 0.35, p<0.01) and protein C (OR 0.38, p=0.02) remained associated with mortality 4) Adjusting specifically for IL-6 levels attenuated FV and FVIII, but not FVII or Protein C, associations.

Conclusions: Findings support that hypercoagulation contributes to disease risk via alterations in the profile of extrinsic pathway coagulation factors, mediated by inflammation (e.g., FVIII) and hepatocyte dysfunction (e.g., protein C). Studies are needed to further clarify mechanisms by which alterations in coagulation biology leads to disease among treated HIV patients.

757 Correlates of Inflammatory Markers After One Year of Suppressive Antiretroviral Treatment (ART)

Supriya Krishnan1, Ronald J. Bosch1, Benigno Rodriguez2, Peter W. Hunt3, Cara Wilson4, Steven G. Deeks1, Michael M. Lederman1, Alan L. Landay1, Allan R. Tenorio5

1Harvard School of Public Health, Center for Biostatistics in AIDS Research, Boston, MA, United States, 2Division of Infectious Diseases and HIV Medicine, Case Western Reserve University School of Medicine, Cleveland, OH, United States, 3Positive Health Program, Department of Medicine, San Francisco General Hospital, University of California, San Francisco, CA, United States, 4Division of Infectious Diseases, University of Colorado Hospital, Denver, CO, United States, 5Department of Immunology and Microbiology, Rush University Medical Center, Chicago, IL, United States

Background: Elevated levels of inflammatory markers such as interleukin (IL)-6 are associated with HIV-associated non-AIDS morbidity and death. Traditional risk factors such as substance use, obesity, triglycerides, cholesterol and fasting glucose levels are likely increased in HIV+ adults, and may be causally related to inflammation. We examined the cross-sectional association between a panel of inflammatory markers, and metabolic and other risk factors in a well-treated HIV+ adult population.

Methodology: A previously described case-control study was performed on HIV+ adults enrolled in the ACTG-ALLRT cohort who were ART naïve at study entry, received a modern ART regimen, and were virally suppressed (<400 copies/ml) at year 1 of ART. This analysis examined the controls that were the event-free comparator population. Spearman correlations (unadjusted and partial) evaluated biomarkers and selected behavioral, metabolic and anthropometric factors at year 1.

Results: Subjects (N=315) were 85% male; mean age was 44 years. At year 1, 59% had CD4 > 350 cells/mm3, 89% had HIV RNA < 50 copies/ml. After adjusting for CD4 and other factors, levels of plasma IL-6, soluble tumor necrosis factor receptors (sTNFR)-I and II, interferon gamma inducible protein-10 (IP-10), soluble CD14 (sCD14), and D-dimer positively correlated with age (r=0.22, p<.001), waist-hip ratio (r=0.15, p<.01), # cigarettes/day (r=0.19, p<.01) and fasting glucose (FG) (r=0.25, p<.001). Correlations for waist circumference, smoking and FG were significant even after adjustment for each of the other factors. IL-6 levels increased as the number of metabolic syndrome components increased (r=0.15, p<.01). sCD14 correlated with BMI (r=−0.12, p=0.03) and smoking (r=0.29, p<.001). sTNFR-I correlated
with waist-hip ratio (r=0.21, p<.001) and smoking (r=0.18, p<.01). sTNFR-II correlated with waist circumference (r=0.15, p=0.01), waist-hip ratio (r=0.21, p<.001), smoking (r=0.24, p<.001), FG (r=0.14, p=0.03) and triglyceride levels (r=0.20, p<.001). None of factors examined gave significant correlations for D-dimer and IP-10.

Conclusions: As in the general population, increased age, increased central obesity and smoking are associated with increased levels of soluble inflammatory markers in HIV+ virally suppressed patients. These findings underscore the relationships between inflammation and behavioral, anthropometric and metabolic risks in treated HIV infection. Future studies should focus on determining the mechanisms for these associations, and whether the impact of inflammation on disease progression is independent of these factors.

758 Pro12Ala Polymorphism Is Associated With Metabolic Disturbance in HIV/HCV Coinfected Patients

Pilar García-Broncano1, Juan Berenguer1,2, Amanda Fernández-Rodríguez1, Daniel Pineda-Tenor1, Marí a Jiménez-Sousa1, Mónica García-Álvarez1, Teresa Aklamiz-Echevarría1,2, Juan Carlos López2, Dariela Micheloud4, Salvador Resino5

Background: Peroxisome proliferator-activated receptor gamma-2 gene (PPARγ2) rs1801282 (Pro12Ala) polymorphism has been associated with lower risk of metabolic disturbance and atherosclerosis. The aim of our study was to analyze the association between the PPARγ2 rs1801282 polymorphism and metabolic disturbance in human immunodeficiency virus (HIV)/Hepatitis C virus (HCV) coinfected patients.

Methodology: A cross-sectional study in 257 non-diabetic HIV/HCV-coinfected patients from Hospital Gregorio Marañón (Madrid, Spain) was carried out between September 2009 and July 2009. Genotyping was performed by using GoldenGate® assay with VeraCode® Technology in Centro Nacional de Genotipado (CeGen). Besides, were analyzed serum lipids (cholesterol, triglycerides, high-density lipoprotein (HDL-C), low-density lipoprotein (LDL-C), LDL-C/HDL-C ratio, and atherogenic index (AI)), and homeostatic model assessment (HOMA) values. Only 207 patients were performed liver biopsy, which were classified according to escala META VIR score, and in 109 of 207 patients were evaluated serum adipokines (leptin, adiponectin, resistin, plasminogen activator inhibitor-1(PAI-1), hepatic growth factor (HGF), and nerve growth factor (NGF)) by multiplex LINCOPLEX™ assay with Luminex 100™ analyzer. The genetic association study was carried out according to a dominant genetic model of G allele (CC vs. CG/GG), which was the model that best fit to our data. Univariate and Multivariate Generalized Linear Models (GLM) were used to study the PPARγ2 polymorphism effect on different clinical variables (lipid profile and IR).

Results: rs1801282 CG/GG genotype (Ala variant) was associated with low values of cholesterol (arithmetic mean ratio (AMR)=0.87 (95% of confidence interval (95%CI)=0.79; 0.96); p=0.004), LDL-C (AMR=0.79 (95%CI=0.68; 0.93); p=0.003), LDL-C/HDL-C (AMR=0.83 (95%CI=0.71; 0.99); p=0.034), and AI (AMR=0.84 (95%CI=0.75; 0.99); p=0.042). Furthermore, rs1801282 CG/GG genotype (Ala variant) was associated with low values of HOMA (AMR=0.71 (95%CI=0.50; 0.99); p=0.048) among patients with significant liver fibrosis (F=2). Moreover, rs1801282 Ala variant was also associated with low serum levels of HGF (AMR=0.61 (95%CI=0.39; 0.94); p=0.028), and NGF (AMR=0.47 (95%CI=0.26; 0.84); p=0.010).

Conclusions: The presence of PPARγ2 rs1801282 CG/GG genotype (Ala variant) was associated with a protective effect for metabolic disturbance versus CC genotype in HIV/HCV coinfected patients. Thus, PPARγ2 rs1801282 polymorphism may play a significant role in the development of metabolic disorders in HIV/HCV coinfected patients, and might have an influence on the cardiovascular risk.

759 Predictors of Incident Hypertension in HIV-Positive Adults Over 24 Months On ART in South Africa

Alana T. Brennan1, 2, Matthew P. Fox1,2, Mhairi Maskew1, Ian Sanne1, 2, Prudence Iv4, Julia Rohr1, 2, Lawrence Long2, Sydney Rosen1, 2

1Center for Global Health & Development, Boston University, Boston, MA, United States, 2Department of Internal Medicine, School of Clinical Medicine, Faculty of Health Sciences, Health Economics and Epidemiology Research Office, Johannesburg, South Africa, 3Department of Internal Medicine, School of Clinical Medicine, Faculty of Health Sciences, Clinical HIV Research Unit, Johannesburg, South Africa

Background: As the current HIV population ages and access to antiretroviral therapy (ART) increases in resource-limited settings, the number of patients developing non-communicable chronic diseases on ART will also increase. In view of limited research on this topic in resource-limited settings, we sought to examine predictors of hypertension in a large urban HIV clinic in South Africa.

Methodology: Prospective study of hypertension over 24 months on ART among 12376 ART naïve adults initiating ART at Themba Lethu Clinic in Johannesburg between April 2004-2011. Participants with hypertension at ART initiation were excluded. We used Cox proportional hazards regression to examine demographic and clinical characteristics at ART initiation in relation to incident hypertension. We first defined hypertension as systolic >140 and/or diastolic BP >90-99.9 mmHg) or moderate/severe (systolic BP >160 and/or diastolic BP >100 mmHg). Person-time started at ART initiation and ended at the earliest of hypertension, loss, death, transfer or completion of 24 months of follow-up.

Results: Among 17 378 eligible patients, 29% (5002) had documented hypertension at ART initiation. The remaining 12 376 were predominately female (62%) and on stavudine-lamivudine-efavirenz (75%). At ART initiation patients had a median age of 36 years (IQR: 31-42), median CD4 count of 94 cells/mm3 (IQR: 35-166), median systolic blood pressure of 113 mm/Hg (IQR: 103-123) and median diastolic blood pressure of 73 mm/Hg (IQR: 66-80). By 24 months, 2116 (17%) developed hypertension, of whom 1857 (88%) were mild and 259 (12%) were moderate/severe. Regression models showed older patients (≥40 years), males, and patients with a BMI ≥25 kg/m² had an increased rate of hypertension over 24 months (Table). Results for mild hypertension were similar, while results for moderate/severe hypertension showed a higher hazard for patients ≥50 years and those with a BMI ≥35 kg/m².
Conclusions: 20% of patients in our cohort developed hypertension within 24 months on ART. Obese patients (BMI ≥30 kg/m²) and those older >40 years of age should be targeted for frequent BP monitoring and identification of other cardiovascular risk factors in order to implement lifestyle modifications and pharmaceutical therapy as indicated to help prevent myocardial infarction, heart failure, stroke and kidney disease.

Frailty, Inflammation and Mortality Among Aging HIV-Infected and At-Risk Injection Drug Users

Damani A. Piggott, Ravi Varadhan, Shruti H. Mehta, Todd T. Brown, Sean X. Leng, Gregory D. Kirk
Johns Hopkins University, Baltimore, MD, United States

Background: Serum measures of inflammation increase with age and have been strongly associated with adverse clinical outcomes among both HIV-infected and uninfected adults. Yet, limited data exists on the potential predictive and clinical utility of aggregate measures of inflammation. Recently, a simple additive index has been validated to best capture the effect of inflammation on mortality among adults 65 years of age and older. Frailty is an age-related syndrome of increased vulnerability to adverse clinical outcomes. Previously, we observed a significant association of frailty with both HIV and mortality risk among aging injection drug users (IDUs). In this study, we evaluated the relationship of frailty with the validated inflammation index and examined the independent effect of this index on mortality.

Methodology: Frailty was defined in the ALIVE cohort of current and former IDUs by the presence of ≥3 of 5 standard criteria: weakness (grip strength), slow gait speed, weight loss, low physical activity, and exhaustion. An inflammatory index score was constructed from serum measures of interleukin-6 (IL-6) and soluble tumor necrosis factor-α receptor-1 (sTNFR1): (log IL-6 + 2*log sTNFR1)/3. Multinomial logistic regression was used to assess the relationship of frailty with inflammation. Mortality was ascertained for the period 2005 through 2010 through linkage to the National Death Index. Cox proportional hazards models were used to estimate the risk (hazard ratios [HR] with 95% confidence intervals [CI]) for all-cause mortality.

Results: Among 1326 subjects, the median age was 48 years, 88% were African American, 457 (34%) were female, and 387 (29%) were HIV+. In separate models, adjusting for sociodemographics, comorbidity, and HIV status, frailty was significantly associated with log IL-6 + 2*log sTNFR1/3. Multinomial logistic regression was used to assess the relationship of frailty with inflammation. Mortality was ascertained for the period 2005 through 2010 through linkage to the National Death Index. Cox proportional hazards models were used to estimate the risk (hazard ratios [HR] with 95% confidence intervals [CI]) for all-cause mortality.

Conclusions: A recently validated, simple, biologically informed inflammatory index is strongly associated with frailty and independently associated with mortality risk among aging HIV-infected IDUs, independent of HIV disease stage. Further studies of the clinical utility, biological underpinnings, and potential therapeutic targets related to this index may ultimately facilitate improved clinical management for aging HIV-infected persons.
763  Brisk Walking Improves Inflammatory Markers in cART-Treated Patients
Valeria Longo1, Matteo Bonato2, Simona Bossolasco1, Laura Galli1, Andrea Caumo2, Gaspare Pawel1, Adriano Lazzarin1, Giampiero Merati1, Antonio La Torre1, Paola Cinqué1
1Infectious Diseases, San Raffaele Scientific Institute, Milano, Italy; 2Biomedical Sciences for Health, Università degli Studi di Milano, Milano, Italy; 3Pathophysiology and Transplantation Department, Università degli Studi di Milano, Milano, Italy

Background: Low grade chronic inflammation is a predictor of cardiovascular disease and metabolic problems, which are frequent complications in patients receiving combination antiretroviral therapy (cART). The aim of this study is to evaluate the benefit of brisk walking as moderate intensity exercise, with or without strength exercise, on metabolic and inflammatory parameters in cART-treated patients.

Methodology: We enrolled 50, HIV-infected cART-treated, sedentary subjects in a 12-week exercise program, consisting of 3 outdoor sessions/week of 60 min walking at 65-75% of HR (Heart Rate) max with (“walk”/strength” group) or without (“walk” group) 30 min circuit training at 65% of 1-RM (Repetition Maximum). Subjects were assessed at baseline (BL) and 12 weeks (W12) by 6-minute walking test (6MWT) and 1-RM test, morphometric measures (BMI, waist, hip and leg circumferences), blood examination (cytometry, fasting total, HDL and LDL cholesterol, tryglicerides, glucose, insulin, AST/ALT, gGT, CPK, HbA1c, CD4 and CD8 cells, plasma HIV-RNA) and body mass distribution by DEXA. We measured traditional markers of chronic immune activation (IL6, d-dimer and sCD14), and IL-18 and myostatin, as potential negative regulators of adipose tissue and muscle homeostasis, respectively. Statistical analysis was performed by Wilcoxon-signed paired rank test and Spearman’s correlation.

Results: 35/50 subjects (26 men, 9 women; median age 48 yrs) completed the 12-week program: 21 in the “walk” group and 14 in the “strength-walk” group. At W12, participants showed significant improvement of performance at 6MWT (P<0.0001) and in all strength exercises (crunch p=0.0002, lat machine p=0.0022, chest press p=0.0007, leg extension p=0.014, sitting calf p=0.0004, leg press p=0.002); of BMI (p=0.004), waist (p=0.050) and hip (p=0.041) circumferences; total (p=0.0004) and LDL cholesterol (p=0.0004). Significant level reductions were observed for d-dimer, IL-18, IL-6 and myostatin (Table 1). No intercorrelations were observed between % changes at W12 of each marker.

Conclusions: Moderate intensity exercise improved aerobic fitness and metabolic markers in cART-treated patients, and it was associated with improvement of immune activation markers and, possibly, adipose tissue and muscle homeostasis.

764  Cell-Mediated CMV Responses in HIV-Infected Persons With Impaired Physical Function
Kristine M. Erlandson, Amanda A. Allshouse, Rick Rapaport, Brent E. Palmer, Cara C. Wilson, Samantha MaWhinney, Thomas B. Campbell
University of Colorado Anschutz Medical Campus, Aurora, CO, United States

Background: Immune responses to human cytomegalovirus (CMV) increase with age and HIV-infection and correlate with cardiovascular disease markers. We previously demonstrated greater odds of functional impairment among HIV-infected persons with higher CMV IgG concentrations, immune activation (%CD38HLA-DR on CD8+ T cells) and inflammation (IL-6, TNF-alpha). Here we evaluated the hypothesis that cell-mediated CMV responses were associated with functional impairment and inflammation/activation in persons aging with HIV infection.

Methodology: Case-control study of 45-65 year-old HIV-infected subjects, on antiretroviral therapy >6 months, plasma HIV-1 RNA <48 c/mL. Low function (LF) cases and high function (HF) controls were identified by clinical criteria, and matched by age, gender, and time since HIV diagnosis. CMV-specific T cell responses were determined by the proportion of CD4+ and CD8+ T cells expressing IFN- after stimulation with CMV pp65 peptides and described using geometric mean and 95% confidence intervals (CI). Odds of LF was estimated by conditional logistic regression. Associations between continuous variables were described by Spearman correlation.

Results: 30 LF cases were matched to 48 HF controls; mean (SE) age 53 ± 0.8 years; 21% female; 76% Caucasian and 17% Hispanic. Compared to controls cases had similar current CD4 (549 ± 49 vs 639 ± 40 cells/μL, p=0.16), lower nadir CD4 (110 ± 27 vs 178 ± 22 cells/μL, p=0.04) and greater smoking prevalence (48% vs 20%, p=0.01). As previously reported, higher CMV IgG was associated with a 5-fold greater odds of LF (CI 1.5, 17.0) per log10 increase in CMV IgG (p=0.01) and was correlated with markers of inflammation: IL-6 (r=0.37, p<0.001), hs-CRP (r=0.29, p=0.01), TNF-alpha (r=0.24, 0.04); activation: %CD38+HLA-DR+ CD8+ T cells (r=0.21, p=0.07); and immune senescence: %CD28-CD8+ T cells (r=0.27, p=0.02). Odds of LF were not significantly different by CMV-specific CD8+ T cells (1.08; 0.92, 1.28; p=0.35) or CD4+ T cells (OR 0.99; CI 0.76, 1.29; p=0.95). Correlation was detected between CMV IgG and CMV-specific CD8+ T cells (r=0.30, p=0.007) but not CMV-specific CD4+ T cells (r=0.17, p=0.15). CMV-specific CD8+ T cells were not correlated with inflammation, activation, or senescence markers; all r≤0.121, p≤0.31. CMV-specific CD4+ T cells were correlated with CD28-CD4+ T cells (r=0.37; p<0.001), but not inflammation or activation markers; all r≤0.111, p≥0.36.
Presence of the Immune Risk Phenotype and Telomere Shortening Among HIV Treated Patients

Patricia Ndumbi, Julian Falutz, Jason Szabo, Orin Rosengren, Christos M. Tsoukas
Immune Deficiency Treatment Centre, McGill University Health Centre, Montreal, QC, Canada

Background: Although effective combination antiretroviral therapy (cART) increases levels of CD4+ T-cells, other T-cell phenotypic alterations often persist in the long-term. These phenotypic abnormalities resemble the Immune Risk Phenotype (IRP) observed in elderly uninfected individuals that have a high risk of morbidity and mortality. The IRP consists of immunologic and serologic markers that include: low CD4:CD8 T-cell ratio (<1), high CD28-negative T-cell percentages and CMV IgG seropositivity. The IRP is also associated with immune senescence yet it has never been evaluated among HIV patients. In this pilot study, we investigated the prevalence of the IRP among successfully treated HIV patients and assessed how this phenotype relates to markers of immune senescence such as telomere shortening.

Methodology: The IRP prevalence was evaluated in 126 successfully treated HIV patients and in 21 age-matched controls. Patients and controls were assessed for CMV serology, CD4:CD8 ratio and CD4+CD28- T-cells percentages. All HIV patients had undetectable viral loads at the time of evaluation. Individuals with clinical manifestation of CMV disease were excluded from the study. Telomere length was measured by Flow-FISH analysis in a subset of 24 HIV patients which were categorized into 2 groups based on their IRP status: “HIV-IRP” (n=13) and “HIV-nIRP” (n=11). All comparisons between groups were performed using the Mann Whitney test and p-values <0.05 were considered significant.

Results: We found that 32% (40/126) of the HIV patients (median age [IQR] =53 [47-60]) exhibited the immunologic and serologic characteristics described in the IRP. None of the controls exhibited an IRP profile (median age [IQR] =55 [47-63]). The median relative telomere length (RTL) was shorter in the HIV-IRP group than in the HIV-nIRP group (median RTL [IQR] = 9.9 [8.7-10.7] and 10.9 [10.3-12], respectively). This difference approached statistical significance (p=0.087).

Conclusions: We have shown for the first time that the prevalence of the IRP among successfully treated HIV patients is significantly higher than in age-matched healthy controls. These findings suggest that this immune profile previously identified in elderly uninfected individuals, occurs at a much younger age in HIV patients. We also found that among those with HIV, there may be an association between the IRP and shorter telomere length. However larger studies will be needed to substantiate this finding and to determine whether the IRP may also represent a risk profile associated with higher mortality/morbidity in the HIV population. This is the first study assessing the association between telomere length and the IRP in the context of HIV.

Geriatric Syndromes Are Common Among Older HIV-Infected Adults

Meredith Greene1-2, Victor Valcour1-2, Yinghui Miao1-4, Ken Covinsky1-2, Joy Madamba5, Monica Mattes6, Harry Lampiris2-7, Jeffrey Martin4, Steven Deeks5
1Medicine-Geriatrics, University of California San Francisco, San Francisco, CA, United States, 2San Francisco VA Medical Center, San Francisco, CA, United States, 3Neurology, University of California San Francisco, San Francisco, CA, United States, 4NCIRE, San Francisco, CA, United States, 5Medicine-HIV/AIDS, University of California San Francisco, San Francisco, CA, United States, 6Medicine-Infectious Diseases, University of California San Francisco, San Francisco, CA, United States, 7Epidemiology & Biostatistics, University of California San Francisco, San Francisco, CA, United States

Background: Geriatric syndromes such as falls, frailty, and functional impairment are multifactorial conditions used to identify vulnerable older adults. We hypothesized that these conditions would be common among virally suppressed HIV-infected older adults and that both HIV and non-HIV related factors would be associated with the presence of geriatric syndromes.

Methodology: We conducted a cross-sectional study within a San Francisco based research cohort of HIV-infected adults age 50 and older who had an undetectable plasma HIV RNA on cART for at least 3 years. We measured frequencies of four geriatric syndromes: (1) falls (yes/no to fall in past year), (2) urinary incontinence (yes/no based on the International Consultation on Incontinence Questionnaire), (3) functional impairment, and (4) frailty (Fried’s criteria). Functional impairment was defined as difficulty with activities of daily living (e.g. dressing, bathing) and instrumental activities of daily living (e.g. shopping, housework). Potential correlates included sociodemographics, number of co-morbidities and non-antiretroviral medications, and HIV specific variables (e.g. proximal and nadir CD4, length of HIV infection, exposure to certain antiretroviral drugs), which were examined in multivariate analyses using relative risk estimation by poisson regression.

Results: 142 subjects were enrolled, of which 94% were male and 63% were Caucasian with a median age of 57 (range 50-74). The median CD4 count was 577 (IQR 393-715), median CD4 nadir was 172 (IQR 50-318), and median length of HIV infection was 22 years (IQR 18-25). 49% had been exposed to zidovudine, stavudine or didanosine. Subjects had a median of 4 (IQR 3-6) co-morbidities and were taking a median of 9 (IQR 5-12) non-antiretroviral medications. 86% of subjects had at least one geriatric syndrome and 54% had 2 or more syndromes. 38 subjects (27%) reported at least one fall, 36 (25%) reported urinary incontinence, and 64 (45%) reported difficulty with at least 1 instrumental activity of daily living. 12 (9%) subjects met the full criteria for frailty, while 79 (56%) met criteria for pre-frailty. Every 50 unit increase in CD4 nadir (RR 0.93, 95% CI 0.88-0.99) and being employed (RR 0.57, 95% CI 0.37-0.89) were associated with a lower relative risk of the composite outcome of 2 or more geriatric syndromes.

Conclusions: In this study population over age 50, more than half of participants had 2 or more geriatric syndromes, which was associated with CD4 nadir. While the role of HIV infection in these syndromes warrants further investigation, the high frequencies of syndromes, especially difficulty with instrumental activities of daily living and pre-frailty, merit consideration of new clinical care paradigms incorporating geriatric medicine principles.
Physical Function Impairment On Quality of Life Among Persons Aging With HIV Infection
Kristine M. Erlandson, Amanda A. Allshouse, Catherine M. Jankowski, Samantha MaWhinney, Wendy M. Kohrt, Thomas B. Campbell
University of Colorado Anschutz Medical Campus, Aurora, CO, United States

Background: Impairments in physical function are seen among aging, HIV-infected persons on effective antiretroviral therapy (ART). The impact of physical function impairments on quality of life (QoL) during ART is unknown.

Methodology: Cross-sectional study of 45-65 year-old HIV-1-infected subjects, on ART >6 months, plasma HIV-1 RNA <48 copies/mL. Medical history, QoL questionnaire (SF-36), and objective physical function assessment for 400-m walk speed (m/sec), power (chair rises/sec), and grip strength (kg) were completed on all subjects. Veterans Aging Cohort Study (VACS) Index scores were calculated as previously described. SF-36 scores were normalized to a population mean of 50 points. Objective physical function, physical activity (>500 versus ≤500 Kcal/week), and VACS scores were used to estimate each QoL subscale in a multivariable linear regression model.

Results: Of 359 subjects, 85% were male, 74% Caucasian, 18% Hispanic, median age 51 (48-56) years, median CD4+ lymphocyte count 551 (361-768) cells/μL, and 5% had detectable HIV-1 RNA. Median SF-36 scores and results of the regression model are shown in the table below. For every 1 m/sec increase in walking pace, we saw an estimated 11.8 point increase in the physical function scale with smaller differences in QoL points across all subscales. For every increase in chair rise pace of 1 rise/sec, we saw an estimated 16.0 point increase in physical function score and 15.0 point increase in social function score with smaller differences in QoL across all subscales. Subjects reporting greater physical activity had QoL scores between 2.8 and 5.7 points higher than those with lower physical activity. A 1 kg increase in grip strength was associated with a 0.2 higher mental health score, but was not significantly associated with differences in other subscales. Inclusion of a comorbidity/mortality index (VACS Index) did not improve the model.

Conclusions: Among aging persons with well-controlled HIV, faster 400-meter walk pace, faster chair rise pace, and greater physical activity were associated with both higher physical and mental QoL, independent of HIV-related mortality risk as estimated by the VACS Index. Targeted exercise programs to increase physical activity and improve speed and power should be evaluated as interventions to improve QoL during ART.

*Units used for the above variables: 400-m walk (1 sec), chair rise (1 rise/sec), grip strength (1 kg), physical activity (>500 or ≤500 Kcal/week), VACS Index (per 10 points). † p<0.05; ‡ p<0.01; †† p<0.001
Methodology: This cohort study includes patients from the control arms of the INSIGHT SMART and ESPRIT studies, all of whom were taking ART following randomization. Participants were included if they did not have a history of diabetes at entry and had IL-6 and hsCRP measured at study entry using stored plasma. Hazard ratios (HR) with 95% confidence intervals (CI) per 2-fold higher level of baseline biomarker levels were estimated using Cox regression adjusting for age, gender, race, use of ART, baseline HIV viral load, CD4+ count, body mass index, hepatitis co-infection, and use of lipid- or blood pressure-lowering treatment. Sensitivity analyses were conducted using SMART patients only who also had baseline lipid levels and smoking assessed.

Results: 3,965 patients with median CD4+ count of 523 cells/mm³ were followed for an average of 4.6 years; 137 patients developed diabetes requiring drug treatment. Higher baseline levels of IL-6, and hsCRP were significantly associated with the risk of developing diabetes. Unadjusted HRs associated with 2-fold higher level of IL-6 and hsCRP were 1.47 (95% CI: 1.26-1.70) and 1.32 (95% CI: 1.20-1.45), respectively. With adjustment for baseline covariates, the associations remained significant (Table). The associations with IL-6 and hsCRP were similar when analyses were restricted to SMART patients and smoking and lipoprotein levels were considered as covariates (HR=1.36; 95% CI: 1.07-1.72 for IL-6 and HR=1.23; 95% CI: 1.07-1.43 for hsCRP).

Conclusions: Elevated levels of CRP and IL-6 predict the development of type 2 diabetes among HIV positive patients taking ART. These data support a possible link between inflammation and the pathogenesis of type 2 diabetes among HIV positive patients.

769 HbA1c Is A Poor Predictor of Fasting Glycemia in HIV-Infected Men With Low CD4 Count, High MCV and MCH

Laurence Slama1,2, Frank J. Palella3, Alison G. Abraham3, Xiuhong Li4,5, Gilles Pialoux1, Lawrence Kingsley1, Jordan E. Lake1, Todd T. Brown1

1Infectious Diseases, Tenon Hospital, Paris, France; 2Infectious Diseases, Feinberg School of Medicine, Northwestern University, Chicago, IL, United States; 3Epidemiology, Johns Hopkins University, Baltimore, MD, United States; 4Biochimie et Hormonologie, Tenon Hospital, Paris, France; 5UPMC Paris 6, UMR_S938, Paris, France; 6University of Pittsburgh, Pittsburgh, PA, United States; 7Infectious Diseases, University of California Los Angeles, Los Angeles, CA, United States; 8Endocrinology and Metabolism, Johns Hopkins University, Baltimore, MD, United States

Background: Hemoglobin A1c (HbA1c) is the primary index of glycemic control in patients with diabetes and is also recommended for diagnosis. There is limited evidence that among HIV-infected patients, HbA1c values may not accurately reflect glycemia. Using data from the Multicenter AIDS cohort Study (MACS) we assessed HbA1c discordance (observed HbA1c - expected HbA1c) and associated factors among HIV-infected participants.

Methodology: Fasting glucose (FG) and HbA1c were measured at each semi-annual MACS visit since April 1999. All HIV-infected and HIV-uninfected men for whom at least one fasting glucose (FG) and HbA1c pair measurement was available were evaluated. Univariate median regression was used to determine the association between HbA1c and FG by serostatus. The relationship between HbA1c and FG in the HIV-uninfected men was used to determine the expected HbA1c. Generalised estimating equation determined factors associated with the HbA1c discordance among HIV-infected men. Clinically significant discordance was defined as observed HbA1c - expected HbA1c ≤0.5%.

Results: Between 1999 and 2012, 1500 HIV-uninfected and 1357 HIV-infected participants were included with a median of 11 visits for each participant. At the baseline visit, 177 had diabetes mellitus (DM); HIV participants were mostly on antiretroviral therapy (ART) (74%) with a median of CD4 cell count at 486/mm³. At a FG of 125 mg/dL, the median HbA1c among the HIV-infected men was 0.21% lower than among the HIV-uninfected men and the magnitude of this effect increased in with FG> 126 mg/dL. 63% of HIV-infected men had at least one visit with clinically significant HbA1c discordance, which was independently associated with low CD4 cell count (<500/mm³), protease Inhibitor, non-nucleoside reverse transcriptase inhibitor or zidovudine-containing regimen, high mean corpuscular red cell volume and abnormal corpuscular haemoglobin.

Conclusions: HbA1c underestimates glycemia in HIV-infected patients and its use may lead to under treatment of established DM or under diagnosis if used as a diagnostic criterion, especially among those with risk factors for HbA1c discordance.

770 Triglycerides/HDL Ratio and Risk of Developing Diabetes Mellitus During Antiretroviral Therapy

Nicola Squillace1, Patrizia Lorenzini2, Giuseppe Lapadula3, Alessandro Cozzi-Lepri4, Stefano Rusconi5, Massimo Puol6, Antonella Castagnaro7, Andrea Antinori1, Andrea Gori1, Antonella d’Arminio Monforte8

1Infectious Disease Unit, San Gerardo Hospital, University of Milano-Bicocca, Monza, Italy; 2“I Lazzaro Spallanzani” National Institute for Infectious Diseases-IRCCS, Rome, Italy; 3Research Department of Infection and Population Health, University College London, London, United Kingdom; 4Department of Biomedical and Clinical Science Luigi Sacco, Infectious Diseases, University of Milan, Milan, Italy; 5Infectious Disease Unit, Niguarda Ca Granda Hospital, Milan, Italy; 6Department of Infectious Diseases, San Raffaele Scientific Institute, University Vita-Salute San Raffaele, Milan, Italy; 7San Paolo Hospital, University of Milan, Milan, Italy

Background: The aim of our analysis was to evaluate the incidence of diabetes mellitus (DM) and its association with triglycerides (TRG), triglycerides to high-density lipoprotein cholesterol ratio (TRG/HDL) and liver fibrosis (measured by FIB-4) during combination antiretroviral therapy (cART).

Methodology: Patients from the ICONA Foundation study initiating first-line cART between 1997 and 2013 were selected and observed up to new-onset DM or last clinical follow-up. DM was defined as: first of 2 consecutive glucose>126 mg/dL or clinical diagnosis of DM or start of anti-diabetes treatment.
Incidence rate was calculated as number of observed DM after cART initiation divided by person years of follow-up (PYFU). Multivariable Poisson regression was used to determine factors independently associated with DM, including current TRG/HDL in model A and current TRG in model B.

**Results:** 3,546 patients [males 73.7%, median age 38 yrs (IQR 33-45), median BMI 23.1 (IQR 21.1-25.2), HCV-ab positivity 22.1%] were included in this analysis. Of these, 80 persons developed DM over 13,911 PYFU, corresponding to an incidence of 5.7 per 1,000 PYFU (95%CI 4.6-7.1). Incidence of DM according to most recent TRG and TG/HDL are shown in Table 1. At multivariable analysis (Table 1 model A) most recent TRG/HDL was associated with a significant increase in risk of developing DM while current TRG was associated with developing DM only at crude analysis (Table 1 model B). Advanced liver fibrosis (defined as FIB-4 index >3.25) was also independently associated with higher risk of DM in model A (Table 1) but not in model B (rate ratio [RR] 2.28; 95%CI 0.89-5.85, p=0.08). However, the association was much stronger among patients without HCV co-infection (RR 5.28; 95%CI 1.25-22.27) than in those with positive HCV-Ap (RR 1.91; 95%CI 0.61-6.0 p-value for interaction=0.02). Other risk factors associated with DM’s onset were (model A): Age (per 10 yrs older) (RR 1.44; 95%CI 1.06-1.95), current BMI>30 (4.85; 95%CI 2.38-9.86 , p<0.001), current D4T+3TC use (6.05; 95%CI 1.87-19.63 vs.TDF+FTC, p<0.05), current ATV+rtv use (3.14; 95%CI 1.27-7.78 vs. EFV, p<0.05).

**Conclusions:** High TRG/HDL ratio predicted the risk of new-onset DM, independently of other traditional risk factors. The use of this simple marker as predictor of the risk of DM merits to be further explored. Advanced hepatic fibrosis estimated using FIB-4 score might be an additional predictor for DM, especially in those with non HCV related liver damage.

771 Measuring Physical Activity and its Impact On Insulin Resistance in MACS Men

Anne K. Monroe1, Todd T. Brown1, Christopher Cox1, Dorothy Wiley1, Frank Palella1, Lawrence Kingsley4, Michael Plankey6

1Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 2Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD, United States, 3UCLA School of Nursing, Los Angeles, CA, United States, 4Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, United States, 5Department of Infectious Diseases and Microbiology, School of Public Health, University of Pittsburgh, Pittsburgh, PA, United States, 6Medicine, Georgetown University School of Medicine, Washington, DC, United States

**Background:** Physical activity (PA) has many beneficial effects, including improved fitness, strength, quality of life, and decreased insulin resistance. Several small studies suggest that HIV-infected adults report inadequate PA. We examined the relationship between HIV status, PA and insulin resistance among men in the Multicenter AIDS Cohort Study (MACS).

**Methodology:** The International Physical Activity Questionnaire (IPAQ short form) was self-administered during MACS visits 53 and 54 (April 1, 2010 to March 31, 2011); we used data from the first administration that could be scored. Per IPAQ protocol, a metabolic equivalents (METs) total score (continuous variable) was calculated by adding MET-minutes/week for all activity performed and a categorical score (low, moderate, and high) was also generated. Concurrent homeostatic model assessment insulin resistance (HOMA-IR) (mmol/L) was calculated as: fasting glucose x fasting insulin)/22.5. Additional covariates included age, race, BMI, education, smoking, HCV status, history of AIDS, ART, CD4, and VL. Adjusted quantile regression was used to investigate the effect of HIV status on PA (continuous). Adjusted linear regression was used to investigate the effect of PA (categorical) on log-transformed HOMA-IR by HIV status.
Results: 1429 men (661 HIV-infected men, 768 HIV-uninfected men) were included in the analysis. HIV-infected status was significantly associated with higher total MET-minutes/week among men reporting the highest activity levels (75th percentile and up). However, the proportion of men reporting low (24% in HIV-infected vs. 23% in HIV-uninfected), moderate (27% vs. 28%), and high (49% vs. 49%) activity was similar by HIV status. Both HIV-infected status and low PA (vs. high PA) were associated with more insulin resistance (p<0.0001 and p=0.0007, respectively). Among men with low PA, HIV-infected men had higher HOMA-IR than their HIV-uninfected counterparts with similar activity levels (p<0.0001). However, this association was not seen among men in the moderate and high PA groups.

Conclusions: In all men, lower PA was associated with more insulin resistance. However, HIV-infected men with the lowest levels of PA were more insulin resistant than HIV-uninfected men with a similarly low PA. This suggests that low PA may affect health outcomes more in HIV-infected persons compared to HIV-uninfected persons and that PA may need to be increased to a greater extent among HIV-infected persons to achieve the same metabolic benefit.

772 Impact of Randomized Antiretroviral Therapy (ART) Initiation On Glucose Metabolism: ACTG A5224s
Kristine M. Erlandson1, Douglas Kitch2, Paul E. Sax3, Eric S. Daar4, Camlin Tierney1, Kathleen M. Melbourne5, Belinda Ha6, Grace A. McComsey7
1University of Colorado Anschutz Medical Campus, Aurora, CO, United States, 2Harvard School of Public Health, Boston, MA, United States, 3Harvard School of Public Health, Boston, MA, United States, 4Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, United States, 5Gilead Sciences, Foster City, CA, United States, 6NHL Research Institute, Research Triangle, NC, United States

Background: Prior studies have found that early HIV protease inhibitors (PIs) and lipodystrophy contribute to glucose dysregulation. Few randomized trials have evaluated glucose indices in ART-naive subjects on newer ARTs.

Methodology: A5202 randomized 1857 ART-naive HIV+ subjects to blinded abacavir/lamivudine (ABC/3TC) or tenofovir/emtricitabine (TDF/FTC) with open-label efavirenz (EFV) or atazanavir/ritonavir (ATV/r). A pre-specified secondary analysis of the metabolic substudy A5224s compared fasting glucose, insulin, and homeostatic model assessment-insulin resistance (HOMA-IR) using 2-sample t-tests, linear regression, and Spearman correlation. Diabetes was defined as 2 fasting glucose values >126 or 2 non-fasting glucose values >200 mg/dL over 1 year.

Results: Overall, 269 non-diabetic subjects enrolled: 85% male, 47% white non-Hispanic, median baseline age 38 years, HIV-1 RNA 4.6 log10 copies/mL, CD4 236 cells/mm3, glucose 84 mg/dL, insulin 4 μIU/mL, and HOMA-IR 0.77. At 96 weeks, the mean (95% CI) glucose increased by 2.7 (1.1, 4.3) mg/dL, insulin by 0.09 (0.03, 0.16) log10 μIU/mL, and log10 HOMA-IR by 0.11 (0.05, 0.18); all p<0.05. Six subjects developed diabetes; glucose changes ranged from -41 to +47 mg/dL. No interaction was detected between nucleoside reverse transcriptase inhibitors (NRTIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) or PI for any glucose index (p≥0.61). Changes in indices were not significantly different between NRTI arms (p≥0.18). Assignment to EFV resulted in greater glucose increase (mean 4.8; 2.6-7.0 mg/dL) compared to ATV/r (0.4; -1.8-2.6 mg/dL); p=0.006. Insulin and HOMA-IR changes were not significantly different (p≥0.72). Multivariable analyses are shown in the table. Glucose change positively correlated with changes in BMI (r=0.23, p=0.001), lean body mass (r=0.19, p=0.006), and trunk fat (r=0.18; p=0.010).

Conclusions: Changes in glucose metabolism were minimal and not significantly different between TDF/FTC and ABC/3TC-based regimens. The small but significantly greater increase in glucose in those assigned to EFV has not been previously reported in a randomized setting of ART-naive persons and may be mediated by change in BMI. As glucose dysregulation may increase with time on ART, longer studies will be needed to further clarify the clinical significance of these findings.

After adjusting for treatment, only variables that remained significant in the final model are shown above.
HIV Infection Increases Risk of Acute Exacerbations of COPD

Allison A. Lambert, Gregory D. Kirk, Jacquie Astemborski, Shruti H. Mehta, M. Bradley Drummond
Johns Hopkins University, Baltimore, MD, United States

Background: Poorly controlled HIV infection is associated with increased risk of COPD. Acute exacerbations of COPD (AECOPD) are major contributors to morbidity and mortality but are understudied in HIV populations. Within the AIDS Linked to the Intravenous Experience (ALIVE) study, we examined the factors associated with AECOPD among those with and at-risk for HIV infection.

Methodology: ALIVE is an on-going prospective, community-based cohort that began following persons with a history of injecting drugs in Baltimore, MD in 1988. We longitudinally examined 167 individuals who had pre-bronchodilator airflow obstruction (defined as forced expiratory volume in 1 second / forced vital capacity [FEV1/FVC] <0.70) on all spirometry measures performed during follow-up. AECOPD, assessed at each 6 month study visit, was defined as answering “yes” to the question “In the last 6 months, have you had a worsening of your breathing status requiring treatment with antibiotics or steroids?” Multivariable logistic regression with generalized estimating equations was used to identify correlates of AECOPD.

Results: A total of 167 participants with a median of 3 visits (IQR 2-5) over 1.5 years (IQR: 0.5-2.1) were included in analysis. The mean age at baseline was 52 years, 89% were black, 30% female and 32% HIV infected with a median CD4 count of 312 cells/mL (IQR: 193-454) and a median viral load of 40 copies/mL (IQR: 40-3627). After adjusting for gender, comorbidity, and COPD severity, HIV infection was independently associated with a 2.49 increased odds of AECOPD (Table 1). Compared to HIV negatives, HIV-infected persons with undetectable (≤40 copies/mL) and high (>10,000 copies/mL) HIV RNA had increased odds of AECOPD, but intermediate RNA levels were not associated (OR 1.23; 95% CI 0.32, 4.67; p=0.76). CD4 count was not associated with increased odds of AECOPD.

Conclusions: HIV infection was independently associated with increased odds of AECOPD. Increased risk for AECOPD at higher and at lower HIV RNA levels likely reflects both biological (immune dysregulation) and behavioral (access to HIV and COPD care) patterns. Providers should be aware that HIV infection may increase the risk for AECOPD.

Association of HIV Infection and Immune Activation With Decline in Lung Function

Kristina Crothers*, Carla V. Rodriguez†, Cherry Wongtrakool‡, Guy Soo Hoo‡, Joon Kim‡, Sheldon T. Brown‡, David Rimland‡, Maria C. Rodriguez-Barradas‡, Matthew B. Goetz‡, Amy C. Justice‡

1Department of Medicine, University of Washington, Seattle, WA, United States, 2Department of Medicine, Atlanta Veterans Affairs Medical Center and Emory University, Atlanta, GA, United States, 3Department of Medicine, West Los Angeles Veterans Affairs Medical Center and David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, CA, United States, 4Department of Medicine, James J. Peters Bronx Veterans Affairs Medical Center and and Icahn School of Medicine at Mt Sinai, New York, NY, United States, 5Department of Medicine, Michael E. DeBakey Veterans Affairs Medical Center and Baylor College of Medicine, Houston, TX, United States, 6Department of Medicine, Veterans Affairs Connecticut Healthcare System and Yale University, New Haven, CT, United States

Background: HIV infection may be a risk factor for chronic obstructive pulmonary disease (COPD), characterized by fixed airflow obstruction (AFO) on spirometry. Decline in the forced expiratory volume in one second (FEV1) is greater in current smokers and in COPD at ~60 ml/year compared to the normal ~30 ml/year decline associated with aging; accelerated FEV1 decline is associated with poor health outcomes. We determined differences in FEV1 decline in HIV-infected (HIV+) compared to uninfected (HIV-) individuals, and the relationship of lung function with systemic biomarkers of inflammation, altered coagulation and immune activation.

Methodology: Longitudinal analysis of HIV+ and HIV- subjects matched for current smoking status enrolled 2009-2012 in the Examinations of HIV Associated Lung Emphysema (EXHALE) Study, a substudy of the Veterans Aging Cohort Study. Subjects completed a standardized baseline questionnaire for lung diseases, smoking and other exposures, and repeated spirometry with bronchodilator (BD) every 6-12 months. Plasma interleukin-6 (IL6),
soluble CD14 (sCD14), and D-dimer were measured at baseline. AFO was defined as a ratio of the FEV1 to forced vital capacity (FVC) <0.70. We used multivariable linear regression models to determine the association of HIV or biomarkers with baseline lung function, and generalized estimating equations (GEE) to determine the association of HIV or biomarkers with change in FEV1.

**Results:** In 168 HIV+ and 147 HIV- subjects, mean age of 54, nearly 60% current smokers, there was no difference in the baseline FEV1 or the prevalence of AFO. However, HIV+ subjects had a 36 ml greater decline in post-BD FEV1 than HIV- subjects (p=0.03) adjusting for age, body mass index, and smoking-pack years, with a median of 3 repeated measures per person over 24 months. Decline in FEV1 was 98 ml/year (standard error [SE] 11) in HIV+ and 62 ml/year (SE 13) in HIV- subjects. Levels of IL6, sCD14 and D-dimer above the group median were independently associated with lower baseline values of FEV1, FEV1/FVC in HIV+ (p<0.05 for all) but not in HIV- subjects in cross-sectional analyses adjusted for race/ethnicity, smoking pack years and injection drug use. Using GEE, sCD14 levels above the group median were independently associated with a greater decline in FEV1 in HIV+ subjects (57 ml/year, SE 22, p<0.01), but not in HIV- subjects in stratified models. In contrast, FEV1 decline was not significantly different by IL6 or D-dimer in either group.

**Conclusions:** Lung function decline, measured by post-BD FEV1, is accelerated in HIV infection, and is associated with elevated levels of sCD14 in HIV+ individuals. These data suggest that selective innate immune activation may play an important role in the progression of COPD in HIV infection.

### 775 HIV Infection and Related Biomarkers Are Independent Risk Factors for Radiographic Emphysema

**Engi F. Attia**1, Matthew B. Goetz2, Maria C. Rodriguez-Barradas1, David Rimland1, Sheldon T. Brown1, Guy Soo Hao2, Joon Kim1, Cherry Wongtrakool1, Kathleen Akgun6, Kristina Crothers1

1Medicine, University of Washington, Seattle, WA, United States, 2Medicine, West Los Angeles Veterans Affairs Medical Center and David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, CA, United States, 3Medicine, Atlanta Veterans Affairs Medical Center and Emory University, Atlanta, GA, United States, 4Medicine, James J. Peters Veterans Affairs Medical Center and Icahn School of Medicine at Mt. Sinai, Bronx and NYC, NY, United States, 5Medicine, West Haven Veterans Affairs Medical Center and Yale University, West Haven, CT, United States

**Background:** The association between HIV infection and emphysema remains incompletely understood. We hypothesized that HIV is an independent risk factor for emphysema severity, and explored whether markers of HIV disease and systemic biomarkers of inflammation (interleukin-6 [IL-6]), altered coagulation (D-dimer) and immune activation (soluble CD14 [sCD14]) are associated with emphysema.

**Methodology:** We performed a cross-sectional analysis of 114 HIV-infected (HIV+) and 89 HIV-uninfected (HIV-) subjects in the Examinations of HIV-Associated Lung Emphysema (EXHALE) study, a pulmonary substudy of the Veterans Aging Cohort Study. All subjects underwent chest CT scan with blinded semi-quantitative interpretation by a radiologist for emphysema severity, graded from 0 to >75% lung involvement, and distribution of emphysema in the upper, mid and lower lung zones. Plasma biomarker levels were measured at enrollment. Demographics, smoking and other exposures were gathered via questionnaires. We generated multivariable logistic regression models to determine the independent risk of HIV with emphysema, defined as >10% lung involvement. We abstracted recent HIV RNA and CD4 cell counts, and nadir CD4 cell counts from VA laboratory data and performed similar analyses to examine the role of HIV related variables and biomarkers among HIV+ subjects.

**Results:** Most HIV+ and HIV- subjects were smokers; those with HIV tended to be older, to have other substance use and prior pulmonary infections. HIV+ subjects were more likely to have greater emphysema severity as well as diffuse and lower lung zone emphysema (Table 1). HIV infection was associated with significantly increased risk for >10% radiographic emphysema in analyses adjusted for pack-years of cigarette smoking (OR 2.24; 95% CI, 1.12 - 4.48). In multivariable analyses restricted to HIV+ individuals, low nadir CD4 (OR 2.98; 95% CI, 1.14 - 7.81) and high sCD14, defined as the upper 25th percentile of values (OR 2.55; 95% CI, 1.04 - 6.22), were associated with increased risk of >10% emphysema. IL-6 and D-dimer levels were not associated with emphysema in HIV.

**Conclusions:** HIV is an independent risk factor for radiographic emphysema, defined by >10% emphysema on CT scan. Emphysema severity was overall significantly greater among HIV+ individuals. Additionally, among those with HIV, nadir CD4 <200 and elevated sCD14 were associated with emphysema, pointing toward potential pathogenic mechanisms linking HIV infection with emphysema.

Background: HIV-infected subjects have been reported to be at higher risk of Chronic Obstructive Pulmonary Disease (COPD) than the general population, due to an increased prevalence and magnitude of exposure hazards, such as smoking, and possible interactions with HIV-infection. We sought to study factors associated with COPD in an HIV-infected cohort with an important smoking history.

Methodology: HIV-CHEST is a multicentre, ongoing prospective study evaluating low dose chest tomography for early lung cancer diagnosis in HIV-infected subjects. A cross-sectional lung function sub-study assessed spirometry and plethysmography in subjects ≥ 40 years, active cigarette smokers or quitted within the past 3 years, ≥ 20 pack-years and with a nadir of CD4 T-cells count < 350/μl. COPD was defined according to the GOLD diagnosis criteria (post-bronchodilator ratio of Force Expiratory Volume in one second (FEV1) to the Force Vital Capacity (FVC) <0.70, graded from 1 to 4). Logistic regression models evaluated the association between COPD and various factors (table). Factors associated with COPD (p<0.2) in univariate analysis were included in the multivariate analysis.

Results: Of 444 subjects included in the prospective study, 353 had a spirometry. Nineteen subjects were excluded, as post-bronchodilator FEV1/FVC was not measured. Median age was 50 years (IQR 46-53), 276 (83%) were men, 330 (99%) were under antiretroviral therapy (ART), median duration of ART was 14 years (IQR 6-16), 84 (25%) had a history of intravenous drugs, 95 (28%) were HCV-infected, median pack-years smoking was 30 (IQR 25-39), 116 (35%) had a history of marijuana use, 294 (88%) had a viral load < 50 copies/ml, and median CD4 T-cells at inclusion and nadir were respectively 574 (IQR 396-764) and 178 (IQR 76-261)/μl. COPD was diagnosed in 83 subjects (25%), of whom 45 (54%) and 34 (41%) were respectively grade 1 and 2; in 62 subjects (75%), COPD was unknown before inclusion. Increased age was associated with COPD while elevated CD4 count was protective (Table).

Conclusions: Prevalence of COPD was high in this smoking HIV-infected cohort and COPD was a new diagnosis in the majority of cases. Potential increased risk with marijuana use deserves further studies. COPD active diagnosis through pulmonary function tests should be advocated in ageing HIV-infected smokers, and smoking cessation highly prioritized.

Factors associated with COPD (n = 334). ART: Antiretroviral Therapy; BMI: Body Mass Index.
Minimal Change in Bone Density and No Association With HIV Factors Over 12 Months in HIV-Infected Men

Amanda Samaranuwickrama, Sophie Jose, Caroline Sabin, Karen Walker-Bone, Martin Fisher, Yvonne Gilleece
1Clinical Investigation and Research Unit, Brighton and Sussex Medical School, Brighton, United Kingdom, 2Research Department of Infection and Population Health, University College London, London, United Kingdom, 3MRC Lifecourse Epidemiology Unit, University of Southampton, Southampton, United Kingdom, 4Department of Infection and Immunity, Brighton and Sussex Medical School, Brighton, United Kingdom, 5Department of HIV and Sexual Health, Brighton and Sussex University Hospitals, Brighton, United Kingdom

Background: It has been postulated that HIV infection is associated with increased risk of osteoporosis, mainly seen in clinical trials. There is a paucity of data in real clinical cohorts. We assessed factors associated with reduced bone mineral density (BMD) at baseline and 12 months in HIV-infected men in our clinic cohort.

Methodology: Longitudinal study of HIV-infected men assessed BMD at baseline and 12 months. HIV demographics, combination antiretroviral therapy (cART) use and osteoporosis risk factors were identified. Absolute BMD (g/cm²) at lumbar spine (LS), total hip (TH) and femoral neck (FN) was measured using dual-energy x-ray absorptiometry (DXA). Reduced BMD was defined as T-score <-1 and >-2.5, and osteoporosis as T-score <-2.5 in men ≥50 years and Z-score <-2 in men <50 years. Men currently or ever taking bisphosphonates were excluded. Change in absolute BMD was assessed using paired t-test. Logistic regression (adjusted for baseline BMD) investigated relationships between risk factors in patients with more than the smallest detectable difference (>SDD) decrease in BMD.

Results: Of 421 men recruited, 21 were excluded for bisphosphonate use. Of 400 men (mean [SD] age 47 [9.8] years, 94% white ethnicity, 93% MSM, diagnosed HIV positive for median [IQR] 9.1 [4.8,15.2] years, median [IQR] CD4 543 [409,694] cells/μL, 92% on cART of whom 88% had HIV RNA <40 copies/mL), 316 had paired DXAs. Baseline prevalence of reduced BMD was 31%, 36% and 47%, and osteoporosis was 10%, 3% and 3% at LS, TH and FN, respectively. Associations with reduced absolute BMD at baseline were low BMI at all sites (p<0.0001), current smoking at TH (p=0.02) and high serum calcium at LS (p=0.02). Over 12 months, mean absolute BMD increased at LS (p=0.006) and decreased at FN (p=0.008), with no significant change at TH (p=0.653) (Table 1). >SDD decrease in BMD occurred in 14%, 10% and 10% at LS, TH and FN, respectively. No factors, including HIV stage, nadir CD4, cART use and type, were associated with >SDD decrease in BMD at any site (all p>0.05).

Conclusions: Although a relatively high proportion of men had reduced BMD, only a minority had a significant decrease over 12 months, with an increase in BMD at LS. We found no association with HIV-related factors, including cART use or type, suggesting that patients on cART have returned to health. Our data suggests that there is no need to alter cART regimens in patients with reduced BMD, but to primarily concentrate on addressing osteoporosis risk factors seen in the general population.

New Fracture Risk and FRAX 10-Year Probability of Fracture in HIV-Infected Adults

Linda A. Battalora, Kate Buchacz, Carl Armon, Edgar T. Overton, John Hammer, Pragna Patel, Joan Chmiel, Kathy Wood, John T. Brooks, Benjamin Young
1Colorado School of Mines, Golden, CO, United States, 2Centers for Disease Control and Prevention, Atlanta, GA, United States, 3Cerner Corporation, Vienna, VA, United States, 4University of Alabama School of Medicine, Birmingham, AL, United States, 5Denver Infectious Disease Consultants, Denver, CO, United States, 6Feinberg School of Medicine, Northwestern University, Chicago, IL, United States, 7International Association of Providers of AIDS Care, Washington, DC, United States

Background: FRAX reliably predicts 10-year fracture risk for adults in the general population. However, its utility for HIV-infected adults, for whom the prevalence of low bone mineral density (BMD) and risk of fractures have been shown to be greater, has not been assessed.

Methodology: Using dual energy X-ray absorptiometry (DEXA) BMD values of the left femoral neck, and clinical data collected prospectively during 2004-2012 from two CDC-sponsored HIV cohorts, we calculated the initial FRAX 10-year risk of a major osteoporotic fracture (i.e., of the hip, spine, forearm, or shoulder). We assessed rates of any new bone fracture and major osteoporotic fracture per 100 person-years (py) of follow-up, stratified by initial FRAX-score intervals, and used Cox proportional hazards models to identify clinical and demographic risk factors for any new fracture.
Results: Among 1006 participants who contributed 5022 py of follow-up, 83% were male, 67% were non-Hispanic white, median age at date of DXA scan was 42 years [interquartile range (IQR) 35-48], and median CD4+ cell count was 408 cells/mm³ [IQR 255-600]. Participants had median (IQR) values of 0.90 g/cm² for BMD (IQR: 0.80-1.00) and 1.9 for FRAX score (IQR: 1.4-3.2); median FRAX scores were higher for those who had any subsequent new fracture vs. those who did not (Wilcoxon rank sum test: p<0.01). (Figure). During a median of 4.2 (IQR 3.0-7.7) years of observation after initial DEXA, 95 participants (9.4%) had any new fracture; 71% occurred among persons with FRAX score <3% (1.39 per 100py) and 15.3% among persons with FRAX score ≥3% (3.27 per 100py). New major osteoporotic fractures were observed among 1.5% of persons with FRAX score <3% (0.30 per 100py), and among 4.9% (1.04 per 100py) of persons with FRAX score ≥3%. In multivariate analyses, having a prior fracture (adjusted hazard ratio [aHR] 2.02, 95% confidence interval [CI]: 1.09-3.71), older age (aHR 1.30 per 10 years, 95% CI: 1.04-1.62), and lower BMD (aHR 0.14 per g/cm², 95% CI: 0.03-0.59) were associated with risk of any new fracture. In a separate model, having FRAX score ≥3% vs. FRAX of < 3.0% was associated with any new fracture (HR 2.31, 95% CI: 1.54-3.46).

Conclusions: In a large convenience sample of relatively young HIV-infected U.S. adults, a FRAX score ≥3%, low baseline BMD, history of prior fracture, and increased age were significantly associated with elevated risk of new fracture.

779LB Bone Density Changes After Antiretroviral Initiation With Protease Inhibitors or Raltegravir

Todd Brown, Carlee Moser, Judith Currier, Heather Ribaudo, Jennifer Rothenberg, Michael Dube, Robert Murphy, James Stein, Grace McCormack

Background: The initiation of antiretroviral therapy (ART) leads to a 2–6% loss of bone mineral density (BMD) over 48–96 weeks which depends in part on the specific medications used. The effect of integrase inhibitors on BMD with ART initiation and how it compares to the changes seen with protease inhibitors (PIs) have not been clearly established.

Methodology: We compared the percentage change in BMD at the lumbar spine, total hip, and total body over 96 weeks in HIV-infected treatment-naïve participants randomized equally to open labeled Tenovir Disoproxil Fumarate–Emtricitabine (TDF/FTC) plus Atazanavir–Ritonavir (ATV/r), Darunavir–Ritonavir (DRV/r), or Raltegravir (RAL) in a substudy of AIDS Clinical Trials Group A5257 (N= 1809) with randomization stratified by substudy participation. BMD was measured using standardized dual-energy x-ray absorptiometry (DXA) and centrally read. We used linear regression with reverse Helmert contrasts to compare the 96-week percentage change in BMD in the two PI arms (ATV/r vs DRV/r) and, if no difference was found, the BMD changes in the combined PI arms were compared to those in the RAL arm. Primary analyses were intent-to-treat, adjusted for the stratification factors of baseline cardiometabolic risk and HIV-1 RNA.

Results: Three hundred and twenty eight participants were randomized and had baseline DXA scans. At baseline, 90% were male and 44% were white, non-Hispanic; the median HIV-1 RNA load was 4.55 log₁₀ copies/mL; age was 37 years; CD4 count was 348 cells/μL. At week 96, the mean percentage changes from baseline in spine and hip were statistically significant in all arms (p<0.001) and similar in the PI arms (Spine: ATV/r -4.0% v DRV/r -3.6%, p=0.42; Hip: ATV/r -3.9% v DRV/r -3.4%, p=0.36), but were greater in the combined PI arms than the RAL arm (Spine: -3.8% v -1.8%, p<0.001; Hip -3.7% v -2.4%, p=0.005). The percentage changes in total body BMD were small, but statistically significant in all of the arms (p<0.001 for all), but the magnitude of the change was greater with ATV/r than DRV/r (-2.9% v -1.6%, p=0.001) or RAL (-1.7%, p=0.004), but not different between the DRV/r and RAL arms (p=0.72). As-treated analyses led to similar results.

Conclusions: In ART-naïve, HIV-infected individuals initiating ART with TDF/FTC, 96 week BMD losses at the lumbar spine and total hip were similar with the PIs, ATV/r and DRV/r, whereas the integrase inhibitor, RAL, had significantly less BMD loss at these sites than the combined PIs arms. In contrast, total body BMD loss was slightly greater with ATV/r than DRV/r.

780 Hand Osteoarthritis, a Joint Disorder Frequent and More Severe in HIV-1 Patients: METAFOB-OA Study

Anne-Laurence Tomi, Jeremy Sellam, Karine Lacombe, Manuela Sebire, Caroline Rey-Jouvin, Anne-Laurence Miquel, Emmanuel Maheu, Pierre-Marie Girard, Jean-Luc Meynard

Background: Osteoarthritis (OA) is one of the most frequent joint disorders, causing chronic pain and functional disability. Accelerated aging and metabolic syndrome (MetS) are common among HIV-infected patients, both of which are risk factors for OA. We investigated whether HIV-1 patients have OA more frequently than the general population and identified risk factors for hand OA (HOA) in the context of HIV.

Methodology: A case control study was designed that included HIV-infected patients with MetS (IDF/AHA criteria) and aged 45 - 65. They were paired with HIV-infected controls without MetS on age, gender, HIV-RNA level and duration of HIV infection. A hand radiograph was performed and analyzed by two independent readers. HOA was diagnosed if the Kellgren-Lawrence score (KL) was ≥2 on ≥1 joint. Thumb base OA (i.e., rhizarthrosis [RZ]) was also evaluated. Structural radiographic severity of HOA, reflecting OA deformity, was assessed by the sum of KL scores across all joints and by the number of joints having KL≥2 on both hands. Prevalence of HOA was compared to that of the literature. Logistic and linear regression models were used to determine risk factors of HOA.

Results: 301 patients [88% male, mean age (SD): 53.4 (5.0) years, mean estimated duration of HIV-infection: 18 (7) years] were included, of whom 152 were cases and 149 were controls. Overall HOA prevalence was 55.6% and was higher in MetS+ (64.7%) than MetS- patients (46.3%), p=0.002. RZ was also more frequently observed in MetS+ patients (26.1 vs 14.1%, p=0.01). Concerning the severity of HOA, mean (SD) sum of KL score was higher
Low Bone Mineral Density Is Associated With Increased Risk of Incident Fracture in HIV+ Adults

Linda A. Battalora1, Kate Buchanan2, Carl Armon3, Edgar T. Overton4, John Hammer1, Pragina Patel5, JoAnn S. Chen6, Tim Bush7, John T. Brooks7, Benjamin Young7
1Colorado School of Mines, Golden, CO, United States, 2Centers for Disease Control and Prevention, Atlanta, GA, United States, 3Cerner Corporation, Vienna, VA, United States, 4University of Alabama School of Medicine, Birmingham, AL, United States, 5Denver Infectious Disease Consultants, Denver, CO, United States, 6Feinberg School of Medicine, Northwestern University, Chicago, IL, United States, 7International Association of Providers of AIDS Care, Washington, DC, United States

Background: Although the prevalence of both low bone mineral density (BMD) and bone fractures are increased among HIV-infected adults compared with the general population, no study has yet characterized their causal association in the context of HIV infection.

Methodology: We analyzed available dual energy x-ray absorptiometry (DEXA) values of the hip (left femoral neck) and clinical data collected prospectively during 2004-2012 from two CDC-sponsored HIV cohort studies, the HOPS and the SUN Study. We assessed factors associated with low BMD (osteopenia or osteoporosis, defined by T-scores of -1.0 to > -2.5, and ≤ -2.5, respectively), using the Jochkheere-Terpstra test for ordered alternatives for continuous variables and the Cochran-Armitage test for categorical variables. We analyzed the association of low BMD with subsequent incident fractures using Cox proportional hazards regression.

Results: Among 1008 patients (median age 42 [interquartile range (IQR)35-48] years, 83% male, 67% non-Hispanic white, median CD4+ cell count [CD4] 408 cells/mm3 [IQR 254-598]), 36.3% (n=366) had osteopenia and 2.9% (n=29) osteoporosis. During 5,032 person-years of observation after DEXA scanning, 95 incident fractures occurred, predominantly rib/sternum (n=18), hand (n=17), foot (n=15) and wrist (n=11). Low BMD was significantly (p<0.05) associated with age, lower nadir CD4, history of fracture, and male-male sex HIV transmission risk. In unadjusted analyses, age, current or prior tobacco smoking, hepatitis C co-infection, history of fracture, and low BMD (osteopenia or osteoporosis) were significantly associated with increased hazard of a new fracture. In multivariable analyses, only osteoporosis (adjusted hazard ratio [aHR] 3.04, 95% confidence interval [CI] 1.47-6.30) and age (aHR 1.35 per 10 years, 95% CI 1.07-1.70) remained associated with incident fracture.

Conclusions: In a large convenience sample of relatively young HIV-infected adults in the U.S., low baseline BMD and increasing age were strongly associated with elevated risk of incident fracture, highlighting the potential value of DEXA screening in this population.

A Randomized Open Label Study for Comparing Two Doses of Zoledronic Acid in HIV Infected Patients

Eugenia Negredo1, Anna Bonjoch1, Nuria Pérez-Álvarez1, 2, Arrelly Ornellas1, 3, Jordi Puig1, Cristina Herrero1, Patricia Echeverría1, Bonaventura Clotet1, 4
1Ullast Contra la Sida Foundation, Germans Trias i Pujol University Hospital, Badalona, Spain, 2Statistics and Operations Research Department, Universitat Politècnica de Catalunya, Barcelona, Spain, 3Department of Econometrics, University of Barcelona, Barcelona, Spain, 4Irsicaixa Foundation, Germans Trias i Pujol University Hospital, Badalona, Spain

Background: An increasing proportion of HIV-infected patients need treatment for osteoporosis. The best management of this problem is not well-known.

Methodology: This is a randomized, controlled, pilot study to compare the benefit of a biennial use of zoledronic acid with the standard dosage, the annual use, in HIV-infected patients with osteoporosis. A total of 31 caucasian subjects were randomized (2:1), 10 at Control group and 21 to Zoledronic group; at week 48, subjects from the Zoledronic group were reallocated to Annual group (n= 12, 5 mg per year, 2 doses in 2 years) or Biennial group (n=9, one dose in 2 years). Changes from baseline to week 96 in bone mineral density (BMD) for the lumbar spine (L1-L4) and total femur, determined by dual-energy x-ray absorptiometry, were compared between groups, as well as changes in serum alkaline phosphatase, serum procollagen type 1 amino-terminal propeptide (P1NP) and urine N-telopeptide of type 1 collagen (NTx). Mann-Whitney test was used to compare the percentage of change in BMD between groups; McNemar test when the variables are categorical, and by Wilcoxon test in case of non normal variables were used for intragroup comparisons.

Results: At week 96, the percentage of change in hip BMD was 2.12% (-0.12; 3.08) in Control group, 5.16% (3.06;6.74) in Annual group and 4.47% (1.58) in Biennial group (p=0.042 between Control and Annual group). Lumbar spine BMD decreased -1.74% (-2.56;3.60) in Control group, increased 7.90% (4.20;16.57) in Annual group and 5.22% (2.02;7.28) in Biennial group (p=0.003 between Control and Annual group; p=0.017 between Control and Biennial group). NTx (p=0.006) and P1NP (p=0.005), significantly decreased in Annual group. Biennial group showed a significant decrease from baseline to 48 week in P1NP (p=0.038), and a trend to significance in NTx (p=0.03), but not between baseline to week 96. No differences between Annual and Biennial groups were detected in any parameter at week 96. Two patients from Zoledronic group suffered grade 1 asthenia and two had fever within 48 hours after the infusion administration, one of them with grade 1 and other grade 2 of intensity. All symptoms reverted with paracetamol or ibuprofen administration. No discontinuations of the study were observed due to adverse events drug-related.

Conclusions: The use of biennial zoledronic acid presented similar bone benefit than the annual administration after 96 weeks of follow up in terms of BMD and bone markers. The biennial administration of zoledronic acid may be an alternative in the treatment of osteoporosis in this population.
783  **Mechanism of Bone Disease in HIV and HCV: Impact of Tenofovir Exposure and Severity of Liver Disease**

James Cutrell1, Naim M. Maalouf1, Song Zhang2, Henning Drechsler1, Ang Gao3, Pablo Tebas2, Roger Bedimo1

1Infectious Diseases, VA North Texas Health Care System, Dallas, TX, United States, 2Center for Mineral Metabolism, University of Texas Southwestern Medical Center, Dallas, TX, United States, 3Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX, United States, 4Infectious Diseases, University of Pennsylvania, Philadelphia, PA, United States

**Background:** Both HIV and HCV infections are associated with an increased risk of osteoporotic fractures. The mechanisms underlying this higher risk are incompletely elucidated. In this analysis, we explore the effects of HIV, HCV and HIV/HCV co-infection on bone health, and assess the relative contributions of TDF exposure and severity of liver disease.

**Methodology:** This prospective, cross-sectional study recruited 298 male volunteers with HIV, HCV, HIV/HCV co-infection and non-infected controls. All HIV infected patients were virologically suppressed on HAART. Subjects underwent bone mineral density (BMD) testing by DXA scan and measurement of fasting bone turnover markers (BTM) (serum C-telopeptide [CTX] and osteocalcin [OC]). The aspartate aminotransferase-to-platelet ratio (APRI) score was calculated as an indirect marker of hepatic fibrosis. Impact of HIV and HCV infections on BMD was evaluated in multivariate models adjusting for APRI score, BMD exposure (current, past or never), or duration of TDF use, respectively. All models controlled for age, race and BMI.

**Results:** Table 1 presents the multivariate analyses of the associations of HIV and HCV infections on femoral neck BMD. HIV and HCV independently predict lower femoral neck BMD, controlling for age, race and BMI (model 1). APRI did not significantly impact BMD or attenuate the association between HIV or HCV and BMD (Model 2), with similar results observed when analysis was restricted to HIV and HCV/HCV patients (not shown). The effect of HIV on BMD is likely mediated through increased bone turnover: HIV patients had higher levels of CTX (p<0.005) and OC (p<0.001). Furthermore, controlling for OC (model 3) or CTX (not shown) attenuated the association of HIV with BMD. HCV infection did not impact OC or CTX, but was associated with increases in regulatory cytokines OPG (p<0.001) and RANKL (p<0.005). Among HIV and HIV/HCV patients, TDF exposure (current or past) (model 4) and duration of TDF use were associated with lower BMD (p=0.0234). After controlling for TDF exposure, the association of HIV disease with lower BMD was significantly attenuated, suggesting that the observed HIV impact is largely mediated by TDF exposure. Similar associations were observed for total hip BMD.

**Conclusions:** The impact of HIV on BMD appears to be explained (at least in large part) by TDF exposure and higher bone turnover. HIV association with BMD is independent of the severity of liver disease, as measured by APRI score.

784  **Low Bone Mineral Density (BMD) Among Ugandan HIV-Infected Patients On Failing First-Line ART**

Bonnie Wandera1, Fred Ssematula1, Agnes Kiragga2, Jayne Ellis1, Clavy Kityo1, Robert Colebunders3, Nicholas Paton4, Andrew Kambuugi1, Philippa Easterbrook1

1Epidemiology and Biostatistics, Makerere University School of Public Health, Kampala Uganda, 2Infectious Diseases Institute, Kampala, Uganda, 3Infectious Diseases Institute, Kampala, Uganda, 4Infectious Diseases Institute, Kampala, Uganda, 5Joint Clinical Research Center, Kampala, Uganda, 6Institute of Tropical Medicine, Antwerp, Belgium, 7Medical Research Council, London, United Kingdom

**Background:** Both HIV infection and use of ART are associated with increased risk of low BMD. There have been few studies of BMD in sub-Saharan Africa. We examined the prevalence of osteopenia and osteoporosis and factors associated with low BMD among patients failing first-line ART in Kampala, Uganda.

**Methodology:** Sub-study of the Europe - Africa Research Network for Evaluation of Second-line Therapy, EARNEST trial, a large randomized trial of three different second-line ART strategies in protease inhibitor - naïve patients with evidence of first-line ART failure in 5 African countries. BMD was measured using Dual energy x-ray absorptiometry scans (DXA) at lumbar spine (LS) and hip. Data on potential risk factors for low BMD i.e age, CD4 cell count, plasma viral load, Body mass index (BMI), prior ART regimens, alcohol use, and dietary calcium intake were collected. Low BMD was defined as T-score <-1, with osteoporosis and osteopenia less than -2.5 and between -2.5 and -1 respectively. Logistic regression was used to identify factors associated with low BMD (T-score < -1).

**Results:** 181/1200 EARNEST participants from 3 sites in Uganda were enrolled into this sub-study. Of these, 125 (69%) were female (16 (12.8%) post-menopausal), median (interquartile range, IQR) baseline values were: age 35 (31-41) years, duration of 1st line ART 3.7(2.7-5.0) years (30 (16.7%) had
used TDF), CD4 67 cells (35-151), and viral load log 4.9 (4.5-5.3), and a low (<18.5 kg/m²) and high (≥ 25 kg/m²) BMI were present in 19 (10.5%) and 44 (24.3%) of subjects. Median (IQR) BMD for lumbar spine and left hip were 0.94 (0.86-1.03) and 0.91 (0.83-0.99) gms/cm² respectively. A total of 89/175 (50.1%) and 44/176 (25%) had low BMD at the lumbar-spine and hip respectively. The prevalence of osteoporosis was 8% at the LS and 11% at the hip while osteopenia was present in 46.6% and 27.1% at the LS and hip respectively. Low BMD at lumbar spine was associated with both low BMI (adjusted odds ratio [AOR] 3.48; 95% Confidence interval [CI] 1.08-11.2), and high BMI (AOR 0.42; 0.20-0.88) as compared to normal BMI, and use of TDF in first-line regimen (AOR 2.23; 95% CI 0.95-5.28, p= 0.06). At the Hip, a low BMI was predictive of low BMD, (AOR 4.12; 1.51-11.3) while overweight was protective, (AOR 0.39; 0.14-1.07). Age, gender, and CD4 cell count were not associated with low BMD.

Conclusions: More than half of the Ugandan patients failing first line ART had low BMD but osteoporosis was present in < 10%. The prevalence of low BMD in general and osteoporosis was comparable with cross-sectional data from Europe and US. However, in the 10% with a low BMI, there was a 3.5 fold increased risk of low BMD. Subjects with a low BMI and those receiving TDF have an increased risk of low BMD and may need bone health evaluation and close monitoring of their BMD while on ART.

**785 Abacavir and Didanosine Enhance Susceptibility To Acetaminophen-Induced Hepatotoxicity**

Ana Blas-García1,2, Victor M. Víctor1,2, Alberto Martí-Rodrigo1, Lara Millán-Medina1, Nadeza Apostolova1,4, Juan V. Esplugues1,2

1Pharmacology, Faculty of Medicine, University of Valencia, Valencia, Spain, 2FISABIO, Valencia, Spain, 3CIBERehd, Valencia, Spain, 4Unidad Predepartamental de Medicina, Universidad Jaime I, Castellón de la Plana, Spain

**Background:** Liver mitochondrial toxicity induced by nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) is usually associated with disrupted mitochondrial DNA replication. However, mitochondrial dysfunction can also be generated by other mechanisms unrelated to inhibition of Pol-γ. We have analysed the acute effects of clinically relevant concentrations of the most widely used NRTIs on the function of mitochondria and have assessed their impact on the viability of hepatic cells. To explore a possible synergism with other drugs whose hepatotoxicity is attributed to the acute undermining of mitochondrial function, we have also evaluated the effects of NRTIs in combination with acetaminophen (APAP).

**Methodology:** Parameters of mitochondrial function (oxygen consumption, mitochondrial membrane potential - Δψm -, reactive oxygen species - ROS - production, ATP levels) and cellular proliferation/survival (cell count, cell cycle, viability) were assessed in Hep3B cells treated (1-24h) with the pyrimidine analogues Lamivudine, Zidovudine and Emtricitabine, the purine analogues Abacavir (ABC) and Didanosine (ddI), or the nucleotide analogue Tenofovir. Further experiments were performed in the presence of different concentrations of APAP. Data were presented as mean±/−SEM, and their statistical significance versus vehicle was analyzed by one-way ANOVA.

**Results:** Clinical concentrations of ABC and ddI, but not of the other NRTIs, produced an immediate and significant decrease in mitochondrial function, expressed by a concentration-dependent inhibition of oxygen consumption, an increased production of ROS, and a reduction of Δψm and intracellular ATP levels. This mitochondrial dysfunction did not compromise cell survival, as the aforementioned parameters returned to previous values after 24h treatment. However, co-administration of these drugs with APAP concentrations below those considered toxic in hepatic cellular models significantly exacerbated the deleterious effects of both treatments on mitochondrial function (30-40% reduction of Δψm with respect to single treatment) and cellular viability (10-20% decrease with respect to each drug).

**Conclusions:** Among the NRTIs evaluated, only ABC and ddI were deleterious to the mitochondria of hepatocytes, though they did not compromise cell survival at the doses and periods in question. However, liver injury was clearly present when either one of these two purine analogues was administered in combination with subtoxic concentrations of APAP. Our findings are of relevance given the frequent use of APAP by patients taking NRTIs and call for caution regarding the use of these antiretrovirals in combination with other hepatotoxic stimuli owing to mitochondrial interference.

**876 Liver Fibrosis Is Not Uncommon in HIV-Infected Patients Without Viral or Alcoholic Hepatitis**

Anchalee Avihingsanon1,2, Salyavit Jitmitraparn3, Vorapot Sapsirisavat1, Tanakorn Apornpong1, Tawan Mengthisong1, Stephen Kerr1,4, Gail V. Matthews4, Sharon R. Lewin5,6, Kiat Ruxrungtham1,7, and the HIV-NAT 006 study team.

1HIV-NAT, TRCARC, Bangkok, Thailand, 2Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, 3Department of Biochemistry, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, 4Kirby Institute, University of New South Wales, Sydney, Australia, 5Infectious Diseases, Alfred Hospital and Monash University, Melbourne, Australia, 6Centre for Biomedicine, Burnet Institute, Melbourne, Australia, 7Medicine, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand

**Background:** Liver fibrosis in HIV-infected individuals is mostly attributable to hepatitis B (HBV) or C (HCV) co-infection. An association between significant liver fibrosis and diabetes mellitus in an HIV-uninfected population has been reported, but this phenomenon in HIV mono-infected patients has not been well described, and few studies of liver fibrosis in HIV mono-infection have been published from Asia. We determined the prevalence of liver fibrosis assessed by transient elastography (TE, Fibroscan®) and its predictors, among our HIV-infected patients on long term combination antiretroviral therapy (cART) at HIV-NAT, in Bangkok.

**Methodology:** Liver stiffness measurement (LSM) was assessed by TE in 586 (57.5% male) HIV-infected patients without HBV/HCV co-infection; subjects with transaminities >10x upper limit of normal were excluded from analysis. LSM values greater than or equal to 7.2kPa were defined as abnormal. Multivariate logistic regression was performed to identify factors associated with abnormal LSM. Predictor covariates included age, gender, metabolic syndrome, cART regimen, duration of cART, alcohol intake, and smoking.
**Results:** At the time of LSM assessment, median age was 43 years and 21% of patients were aged >50 years. Median (IQR) duration on cART was 11 (6-15) years; median CD4 cell count was 573 (447-730) cells/mm3, median ALT was 27 (20-40) U/L and 95% of patients had plasma HIV RNA <50 copies/mL. Abnormal LSM was observed in 10.9% (64/586) patients and of these, 6 had scores >13kPa indicating cirrhosis. Diabetes mellitus was diagnosed in 18.4% (108/586) patients: 22% (24/108) of patients with diabetes mellitus had abnormal LSM versus only 8% (40/478) of non-diabetic patients (p<0.001). In addition, 24% and 8% of patients with BMI>25kg/m2 and BMI<25kg/m2 had abnormal LSM, respectively. In multivariate analyses, male gender (adjusted odds ratio [OR] 2.10, 95% confidence interval [CI] 1.15-3.80; P=0.015), BMI>25kg/m2 (OR 3.79, 95%CI 2.13-6.73, P<0.01), and diabetes (2.67, 95%CI 1.46-4.88, P=0.001) were independently associated with abnormal LSM. Didanosine use was not significant in univariate models.

**Conclusions:** The prevalence of abnormal LSM among our HIV-infected patients without HBV or HCV in a setting of relatively low alcohol consumption and long duration of cART is substantial. Diabetes, being overweight and male gender were significantly associated with liver damage in this cohort. Since liver fibrosis may progress to cirrhosis, hepatocellular carcinoma and cardiovascular morbidity, diabetic patients and overweight patients should be evaluated for the presence of liver fibrosis. Early diagnosis will enable interventions for modifiable risk factors, including diet, exercise and weight loss.

**Background:** Whilst some antiretroviral (ARV) drugs, including d-drugs (stavudine [d4T], didanosine [ddI], zalcitabine [ddC]), may cause hepatotoxicity, their association with clinically defined ESLD remains unknown. Whilst rarely used in resource-rich settings, d-drugs are still used in some resource-limited settings.

**Methodology:** D:A:D participants were followed from 1/2/2004 to the earliest of ESLD (variceal bleeding, grade III/IV hepatic encephalopathy, hepatorenal syndrome, liver transplant), death, 6 months after last visit or 1/2/2012. Poisson regression described associations between ESLD and cumulative use of d-drugs, other nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors (PIs), non-NRTIs (NNRTIs), and possible confounders (table), and considered whether any drug effects were reversed upon cessation.

**Table:** Associations between current and cumulative exposure to d-drugs and rate of ESLD

*PY: person-years; CI: confidence interval; a adjusted for time since stopping d-drug and cumulative exposure to d-drug; b Age, injection drug use as mode of HIV acquisition, previous AIDS diagnosis, viral hepatitis C/B co-infection, latest CD4 count, time since stopping d-drug and cumulative exposure to d-drug, no significant associations were seen between ESLD and calendar year, gender, cohort, smoking status, ethnicity or latest HIV RNA level and so models do not include adjustment for these factors.*
Results: Over 252,660 person-years (PY), 204 persons experienced ESLD (incidence 0.81/1000 PY [95%CI 0.70-0.92]). Most common ESLD manifestations were encephalopathy (43%) and variceal bleeding (30%); for 91% the underlying cause was viral hepatitis and/or alcohol use. After adjustment, longer d-drug use was associated with increased ESLD rates (overall adjusted rate ratio 1.07 [95% CI 1.02-1.12]/year; 4.35 [1.04-1.16]; ddi 1.06 [1.00-1.12]; ddC 1.07 [0.92-1.24]). In contrast, no associations were seen with longer use of other NRTIs (1.03 [0.98-1.08]), PIs (0.99 [0.95-1.05]) or NNRTIs (0.99 [0.93-1.05]). Of 19,033 persons on d-drugs, 90% stopped their use at least once, with only 22% of the PY in those exposed to d-drugs being in current users. Those stopping d-drugs had higher ESLD rates than those currently on d-drugs; this effect did not wane in the first 8 years after cessation (table). Other ESLD risk factors were older age (>35 vs. <35 years: 2.20 [1.20-4.03]), latest CD4 (0.77 [0.74-0.80]/50 cells higher), hepatitis C (1.66 [1.08-2.55]) and hepatitis B (2.63 [1.63-4.25]) coinfection and injection drug use acquisition mode (4.45 [3.22-6.14]). There was no evidence that the d-drug effect was modified by hepatitis status (p>0.1 for interaction).

Conclusions: Cumulative use of d-drugs, but not other ARV drugs, was associated with increased ESLD rates, which were not reversible upon cessation. The higher rates in those stopping d-drugs may suggest selective discontinuation in those at highest risk of ESLD. Our results suggest that d-drugs should be avoided if possible, particularly in those with viral hepatitis.

788 Microbial Translocation, Immune Activation, Apoptosis and Liver Fibrosis in the MASH Cohort

Marianna K. Baum1, Kenneth E. Sherman1, Sabrina S. Martinez2, Pedro Greer3, Tiffany Stewart1, Christina Jacobs1, Sonya Luisi1, Kimberly Dilorio1, Adriana Campa1
1Stempel College of Public Health and Social Work, Florida International University, Miami, FL, United States, 2Division of Digestive Disease, University of Cincinnati, Cincinnati, OH, United States, 3College of Medicine, Florida International University, Miami, FL, United States

Background: Microbial translocation and immune activation occurs as HIV disease progresses and has been linked with the development of liver disease. Most of these studies however, have been done in vitro and in animal models. Our objective was to investigate the pathways of liver fibrogenesis, including microbial translocation, apoptosis, and cytokine activation in HIV mono-infected and HIV-HCV co-infected adults in the Miami Adult Studies on HIV (MASH) Cohort.

Methodology: After obtaining informed consent in a subset of the MASH cohort participants, blood was collected at baseline and 12 months later for indices of liver fibrosis (FIB-4 and APRI), bacterial translocation (plasma LPS), immune activation (soluble CD14), pro-fibrotic cytokine (TGF-β1), and hepatocyte apoptosis (cytokeratin-18 [CK-18]). FIB-4 and APRI were calculated [age (years) x AST (U/L)/[PLT (10^9 cells/L) X ALT1/2 (U/L)], and [AST (x upper limit of normal range) x 100]/platelet count (10^9 cells/L)], respectively. LPS was determined using the Limulus Amebocyte Lysate kit (Lonza, Wackersville, MD). Soluble CD14 and TGF-β1 were measured using Quantikine ELISA kits (R&D, Minneapolis, MD). Plasma levels of CK-18 were determined by M30 Apoptosense ELISA kit (PEVIVA, Bromma, Sweden). Questionnaires were used for demographics.

Results: Among 80 participants, the mean age was 46.65±7.77, 65% were male, and 75% were black non-Hispanic; 87% were on ART and 25% were HIV/HCV co-infected. Liver fibrosis progressed faster in HIV/HCV co-infected than in HIV mono-infected participants [FIB-4 (2.21±1 SD 1.61 vs 1.21±1 SD 0.44, p=0.02), APRI (0.64 ± SD 0.64 vs. 0.29 ± SD 0.11, p=0.03)]. In a linear regression analysis faster progression of liver fibrosis using either FIB-4 or APRI was associated with higher CK-18; for FIB-4 (β=11.027, p=0.038) and sCD14 (β=0.0006, p=0.029); for APRI the association was CK-18 (β=47.449, p=0.005) and sCD14 (β=0.0002, p=0.042). Soluble CD14 was associated with TGF-β1 (β=2.330, p=0.001). Using mixed models to evaluate change over time, increase in sCD14 was predictive of faster liver fibrosis [FIB-4 (β=0.0005, p=0.040), APRI (β=0.0002, p=0.043)]. Faster disease progression was associated with higher levels of CK-18 over time for both FIB-4 and APRI (β=16.756, p<0.001, and β=37.940, p<0.001). All analyses were controlled for age, gender and CD4 cell count.

Conclusions: Advancement of liver fibrosis estimated by FIB-4 and APRI was associated with increased bacterial translocation, immune activation, hepatocellular apoptosis, and increased level of a pro-fibrotic cytokine TGF-β1, over a period of one year. Larger studies are warranted to increase the understanding of liver fibrogenesis in order to identify pro-fibrotic targets.

789 Cumulative Exposure To Ritonavir-Boosted Atazanavir Is Associated With Cholelithiasis

Takeshi Nishijima1,2, Hiroyuki Gatanaga1,2, Takuro Shimbo1, Yohei Hamada1, Junko Tanuma1, Kunihisa Tsukada1, Katsuji Teruya1, Yoshimi Kikuchi1, Shinichi Oka1
1AIDS Clinical Center, National Center for Global Health and Medicine, Tokyo, Japan, 2Center for AIDS Research, Kumamoto University, Kumamoto, Japan, 3Department of Clinical Study and Informatics, Center for Clinical Sciences, National Center for Global Health and Medicine, Tokyo, Japan

Background: The effect of long-term treatment with ritonav-boosted atazanavir (ATV/r) on cholelithiasis formation is unknown.

Methodology: A single-center, cross-sectional study was conducted to elucidate the prevalence of cholelithiasis in patients with HIV-1 infection who underwent abdominal ultrasonography between January 2004 and March 2012. Uni- and multi-variate logistic regression analyses were applied to estimate the effects of >2 years of ATV/r exposure on cholelithiasis as the primary exposure.

Results: Of the 890 study patients, 84 (9.4%) had >2 years of ATV/r exposure. Cholelithiasis was twice more frequently diagnosed in those treated for >2 years with ATV/r [15 (18%) of 84 patients] than in those treated for <2 years [72 (8.9%) of 806 patients] (p=0.018). Univariate analysis showed a significant association between >2 years of ATV/r exposure and cholelithiasis (OR=2.216; 95%CI, 1.206-4.073; p=0.010), and the association almost persisted in multivariate analysis (adjusted OR=1.806; 95%CI, 0.922-3.537, p=0.085). Treatment for >2 years with ritonav-boosted lopinavir (LPV/r) and ritonavir-boosted darunavir (DRV/r) was not associated with cholelithiasis in uni- and multi-variate analysis (>2 years exposure to LPV/r [n=148 (16.6%)]: OR 1.246, 95% CI 0.710-2.185, p=0.443; adjusted OR 1.221, 95% CI 0.674-2.214, p=0.510] [>2 years exposure to DRV/r [n=29 (3.3%)]: OR 1.067, 95% CI 0.316-3.601, p=0.916; adjusted OR 0.641, 95% CI 0.173-2.377, p=0.506]). Additional analysis showed that >1 year exposure to ATV/r [n=124 (13.9%)] was significantly associated with cholelithiasis (OR 1.857, 95%CI 1.073-3.214, p=0.027), whereas >1 year exposure to LPV/r and DRV/r was not.
**Prevalence of Liver Fibrosis Based On Non-Invasive Markers Among HIV-Infected Patients in Zambia**

Michael J. Vinikoor1,2, Kalo Musukuma1, Gilles Wandelers1, Arianna Zanolini1,2, Aggrey Mweemba1, Carolyn Bolton-Moore1,5, Izukanji Sikazwe1, Benjamin H. Chi1,5, Lloyd Mulenga1,4

1Centre for Infectious Disease Research in Zambia, Lusaka, Zambia, 2Institute of Global Health and Infectious Diseases, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 3Institute of Social and Preventive Medicine, University of Bern, Bern, Switzerland, 4University Teaching Hospital, Lusaka, Zambia, 5Obstetrics and Gynecology, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

**Background:** Liver-related mortality is anticipated to increase as HIV-infected individuals live longer in sub-Saharan Africa (SSA). Data on the epidemiology of liver fibrosis, an early form of chronic liver disease, from these populations are scarce. Using FIB-4 index and AST-to-platelet ratio index (APRI), we estimated the prevalence and factors associated with having significant fibrosis among HIV-infected Zambians.

**Methodology:** Using central laboratory testing data from Lusaka public-sector HIV care facilities, we identified patients with measurements of liver transaminases (AST and ALT) and platelet count within 90 days of enrollment. Among patients with available measurements, we calculated FIB-4 index and APRI using published formulas. We determined the proportion with significant liver fibrosis, defined as having either a FIB-4 >3.25 or APRI >1.5. Using multivariable logistic regression we assessed demographic and medical characteristics associated with fibrosis including age, sex, CD4+ T-cell count, and hepatitis B virus (HBV) status.

**Results:** Of the 87,458 patients who enrolled from July 2006 to July 2008, 35,551 (40.6%) patients had available laboratory testing at enrollment to assess liver fibrosis. The median age of patients was 33 years (interquartile range [IQR], 27-39 years) and 58.2% were women. At enrollment, median CD4+ T-cell count was 220 cells/mm3 (IQR, 103-386 cells/mm3). Only 372 (1.1%) were screened for HBV co-infection with a hepatitis B surface antigen assay. The median FIB-4 index was 0.94 (IQR, 0.61-1.46) and the median APRI was 0.38 (IQR, 0.25-0.64). Significant liver fibrosis was present in 3,008 (8.5%; 95% confidence interval [CI], 8.2-8.8%) of patients. A 5-year increase in age (adjusted odds ratio [AOR], 1.02; 95% CI, 1.00-1.06), male sex (AOR 1.95; 95% CI, 1.72-2.20), and CD4+ T-cell count <200 cells/mm3 (AOR 3.14; 95% CI, 2.75-3.59) were associated with having liver fibrosis. Among those screened, HBV co-infection was also associated with having fibrosis (AOR 2.92; 95% CI, 1.03-8.28).

**Conclusions:** Among HIV-infected adults enrolling in HIV care in urban Zambia, nearly 9% may have significant liver fibrosis, a risk factor for liver-related death. In many SSA settings where liver biopsy is rarely available, dedicated HIV cohorts are needed to investigate the utility of non-invasive liver fibrosis assessment.

**Significance of Alcohol Abuse Diagnosis vs Other Risk Factors for Advanced Liver Fibrosis by FIB-4**

H. Nina Kim1, Heidi M. Crane1, Carla V. Rodriguez1, Stephen Van Rompaey1, W. Christopher Mathews2, Michael Mugavero1, Kenneth H. Mayer4, Katerina Christopoulos5, Sonia Napravnik1, Mari M. Kitahata1

**Background:** Liver disease has emerged as a major cause of non-AIDS-related death among patients with HIV. Given the limitations of liver biopsy, noninvasive markers of hepatic fibrosis such as FIB-4, an index derived from age, platelet count and aminotransferase levels (ALT, AST), have been validated and shown to predict both severity of fibrosis and clinical outcomes. We studied current alcohol use as measured systematically across sites by self-reported clinical assessment, alcohol history as captured by clinician-recorded alcohol diagnoses over time, and other factors such as viral hepatitis and their associations with advanced fibrosis as represented by FIB-4 >3.25 in a large clinical cohort of patients across the U.S.

**Methodology:** All 8,220 patients in the CNICS cohort across 6 sites who completed self-reported assessments as part of routine care and had at least one set of FIB-4 labs were included. The most recent assessment data and lab values were used. Current alcohol use was categorized using AUDIT-C scores. We defined alcohol abuse diagnosis as any diagnosis of alcohol dependence or abuse recorded over time. We examined associations using logistic regression.

**Conclusions:** Long-term treatment of patients with HIV-1 infection for >2 years with ATV/r was associated with increased risk for cholelithiasis compared to patients with shorter exposure. Long-term exposure to ATV/r appears to increase the risk of cholelithiasis in patients with HIV-1 infection.
Predictors of Progression, Stabilisation, or Improvement of eGFR After Chronic Renal Impairment

Lene Ryom\(^1\), Amanda Mocroft\(^2\), Ole Kirk\(^3\), Peter Reiss\(^4\), Michael Ross\(^5\), Olivier Moranne\(^6\), Philippe Morlat\(^7\), Colette Smith\(^8\), Christoph A. Fux\(^9\), Jens D. Lundgren\(^1\), on Behalf of the D:A:D Study Group

\(^1\)Copenhagen HIV Programme and Epidemioklinikken M5132, Rigshospitalet, Copenhagen University Hospital and University of Copenhagen, Faculty of Health and Medical Sciences, Copenhagen, Denmark, \(^2\)Infection and Population Health, University College London, London, United Kingdom, \(^3\)Division of Infectious Diseases and Department of Global Health, Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, \(^4\)Division of Nephrology, Mount Sinai School of Medicine, New York City, NY, United States, \(^5\)Nephrology and Public Health Departments, CHU de Nice, Nice, France, \(^6\)Service de Médecine Intérieure et Maladies Infectieuses, Hôpital Saint-André, CHU de Bordeaux, Bordeaux, France, \(^7\)Clinic for Infectious Diseases and Hospital Hygiene, Kantonsspital Aarau, Aarau, Switzerland

Background: Knowledge of eGFR outcomes after chronic renal impairment (CRI) in HIV-positive persons and its relationship to antiretroviral drug (ARVs) use is limited. Prior studies have shown increased tenofovir (TDF) discontinuation at eGFR<70 mL/min/1.73m\(^2\) limiting the value of eGFR<60 as a CRI cut-off.

Methodology: D:A:D participants were followed from eGFR>80 (Cockcroft-Gault) after 1/1/2004 to CRI, defined as 2 consecutive eGFR ≤70 (>3 months apart), thus ensuring an eGFR decline of ≥10 before CRI. The median of all (and minimum 2) eGFRs at 12-24 months after CRI was compared to the median eGFR defining CRI, and eGFR changes were grouped into: improvement (increase >+10), stabilisation (-10 to +10) and progression (decrease >-10). Multinomial regression assessed odds of better eGFR outcomes (assuming improvement is better than stabilisation, which in turn is better than progression) adjusting for use and discontinuation of TDF, atazanavir (+/- ritonavir, ATV/r), lopinavir (LPV/r), other boosted protease inhibitors (PI/r) and abacavir (ABC), as well as demographics, HIV-related factors, HCV status and traditional renal risk factors (figure).

Results: Of 1237 persons developing CRI, 23.2% improved eGFR, 69.0% stabilised and 7.8% progressed at 12-24 months after CRI. Those on TDF at time of CRI had lower odds of better eGFR outcomes compared to those never exposed to TDF, while those off TDF for ≥12 months at time of CRI had higher odds of better outcomes (figure). Similar trends were seen for ATV/r, LPV/r and other PI/r, but not ATV or ABC. Censoring follow-up for nephrotoxic ARVs used concomitantly (i.e. those on TDF for concomitant ATV/r use) showed similar results. Older persons (adjusted odds 0.61/10 yrs [95%CI 0.50-0.70]) and those with slowly declining eGFR prior to CRI (0.72 [0.55-0.96], ≤10 vs. >10/yr) had significantly lower odds of better eGFR outcomes, while those with diabetes for >5 yrs had marginally significant lower odds compared to non-diabetics (0.61 [0.36-1.05]). No HIV-related factors were associated with better eGFR outcomes.

Conclusions: Use of TDF, ATV/r, LPV/r and other PI/r, older age, diabetes and slowly declining eGFR were associated with decreasing odds of better eGFR outcomes in HIV-positive persons after CRI. TDF discontinuation prior to CRI was associated with better eGFR outcomes, suggesting TDF associated eGFR decline may be halted or reversed with early cessation. There was some suggestion that this may also be true for ATV/r, LPV/r and other PI/r.

ARV Use at CRI and Adjusted Odds Ratios of Better Renal Outcomes

CRI: chronic renal impairment (confirmed eGFR <70). Models adjusted for gender, age, Nadir CD4, baseline CD4, date of CRI, eGFR at CRI, eGFR slope prior to CRI, HCV status (unknown, negative, positive; anti-HCV positive & HCV-RNA positive/unknown), diabetes (no: yes<5 years, yes>5 years), hypertension (>150>100), prior cardiovascular disease.

Use is based on, currently on, currently off of TDF, ATV, LPV, other PI/r and ABC. Indinavir use after 2004 was limited and use was only included to account for possible confounding.
793 Spectrum of HIV-Associated Kidney Disease in the Era of Combination Antiretroviral Therapy

John Booth1, Lisa Hamzah2, Sophie Jose1, Stephen Mcadoo1, Emil Kumar1, Catherine Horsfield1, Patrick O’Donnell1, Rachael Jones1, Caroline Sabin1, Frank A. Post2

1University College London, London, United Kingdom, 2King’s College London, London, United Kingdom

**Background:** Immune complex kidney disease (ICKD) has become the dominant pathology in renal biopsy series of HIV+ patients. The natural history of ICKD and risk factors for ICKD remain poorly studied.

**Methodology:** We reviewed consecutive renal biopsies (1998-2012) of HIV+ patients attending eight clinics in the UK. ICKD was defined by the unequivocal presence of glomerular immunoglobulin deposits and corroborated, where available, by the presence of electron dense deposits on electron microscopy. We compared patients with ICKD to those with HIV-associated nephropathy (HIVAN) and patients in the UK CHIC cohort. Kaplan-Meier analysis was used to estimate progression to end-stage kidney disease (ESKD), and Poisson regression analysis to examine factors associated with ICKD and HIVAN in the UK CHIC cohort.

**Results:** Of the 250 diagnostic biopsies, 88 showed ICKD and 67 HIVAN. ICKD comprised a spectrum of patterns including membranous (n=17), membrano-proliferative (n=5) and ICKD-not otherwise specified [NOS] (n=34); these groups displayed considerable overlap in both glomerular morphology and location of deposits and were hence considered together as ‘core’ ICKD. The remaining ICKD biopsies showed IgA nephropathy (n= 26) and lupus (n=6) nephropathy; these patients were analyzed separately and excluded from the present analyses. Patients with ICKD and HIVAN differed by ethnicity (black: 54% vs. 98%), median known duration of HIV (6.2 vs. 0.1 years), degree of immunodeficiency (median CD4 nadir 155 vs. 54, median CD4 at biopsy 382 vs. 116 cells/mm³) and severity of kidney disease at biopsy (median eGFR 53 vs. 22 mL/min/1.73m²) (p<0.001 for all). At biopsy, 59% vs. 41% of patients had initiated combination antiretroviral therapy (ART) (p=0.01) and 66% vs. 34% had HIV RNA <200 c/mL (p=0.0008); at 1 and 5 years post-biopsy, 4% vs. 29% and 13% vs. 45% of patients had progressed to ESKD (p<0.0001 for both). Of the 31,483 patients in the UK CHIC cohort, 32 developed HIVAN and 44 ICKD during follow up. In multivariable analyses, black ethnicity (IRR 2.23 [1.13, 4.40]) and HIV viraemia (1.48 [1.17, 1.86] per log₁₀ increase in HIV RNA) were associated with ‘core’ ICKD, and black ethnicity (IRR 9.94 [3.69, 26.75]), HIV viraemia (1.35 [1.02, 1.79]), and current CD4 cell count (0.78 [0.68, 0.88] per 50 cell increase) with HIVAN.

**Conclusions:** This is the first study to demonstrate a relationship between HIV replication and ICKD. Compared to HIVAN, ICKD was associated with less advanced immunodeficiency and a lower rate of progression to ESKD. The observed association with HIV viraemia for both ‘core’ ICKD and HIVAN may imply a pathogenic role of HIV replication and its associated immune activation; it also suggests that suppressive ART may reduce the risk of developing these types of kidney disease.

794 Renal and Metabolic Safety of Initial HIV-1 Therapy in Resource-Limited Settings

Francine Touzard Romo1, Laura M. Smeaton1, Thomas B. Campbell1, Cynthia Riviere1, Rosie Mingibisa1, Khuanchai Supparatpinyo1, Johnstone Kumwenda1, Nagalingeswaran Kumarasamy1, James G. Hakim1, Timothy Flanigan1

1The Miriam Hospital, Providence, RI, United States, 2Harvard School of Public Health, Boston, MA, United States, 3University of Colorado Denver, Aurora, CO, United States, 4Los Centres GHESKIO, Port-au-Prince, Haiti, 5University of KwaZulu Natal, Durban, South Africa, 6Chiang Mai University, Chiang Mai, Thailand, 7College of Medicine, Blantyre, Malawi, 8YRSCARE Medical Centre, Chennai, India, 9University of Zimbabwe College of Health Sciences, Harare, Zimbabwe, 10Brown Medical School, Providence, RI, United States

**Background:** Convenient dosing, potency, and low toxicity profile support use of tenofovir disoproxil fumarate (TDF) as the preferred first line nucleotide reverse transcriptase inhibitor (NRTI) in combination regimens for HIV-1 treatment. However, renal and metabolic safety of TDF compared to other NRTI in resource-limited settings has not been well described.

**Methodology:** Secondary analysis within the ACTG A5175/PEARLS trial, examining the renal and metabolic safety outcomes between participants randomized to zidovudine/lamivudine plus efavirenz (ZDV/3TC + EVF) and TDF/emtricitabine plus EFV treatment arms. Adverse event analysis included occurrence of renal abnormalities (Grade ≥ 3 serum creatinine levels or calculated creatinine clearance [CrCl] by Crockoft-Gault method < 50 ml/min), renal and metabolic serious non-AIDS defining events (SNADEs) at study follow up. Logistic regression explored association between baseline covariates and renal abnormalities. Wilcoxon tests compared serum creatinine with urine dipstick results every 24 weeks and response profiles analysis for CrCl levels over time.

**Results:** Twenty-one of 1045 participants developed renal abnormalities through 192 weeks (Table 1): 71% were in TDF arm (p=0.08). History of diabetes (OR: 10.7, 95% CI: 2.2-52.1), history of AIDS event (OR: 2.7, 95%CI: 0.95-57.4) and a lower baseline CrCl (OR: 3.1 per each 25 ml/min decline, 95% CI: 1.8-6.1) were each associated with development of renal abnormalities. Renal SNADEs occurred in 4% of patients, the majority were urinary tract infections (79%). Renal failure was recorded in 4/42 patients with renal SNADEs and only one event was attributed to TDF use. Serum creatinine levels did not significantly differ to urine dipstick results (normal versus abnormal) at any time point. Significantly lower CrCl values were observed in patients receiving TDF compared to ZDV, but magnitude of difference was small (medians ranging from 98 vs. 106 ml/min at 24 weeks; p < 0.001, to 103 vs. 106 ml/min at 96 weeks; p=0.07, repeated measures analysis from baseline p=0.05). Serious metabolic diagnoses were rare but higher in the ZDV arm (3 vs. 20 cases; p<0.001).

**Conclusions:** TDF use was not associated with a significant risk of renal abnormalities or serious renal events compared to ZDV in this randomized, multinational study. However, slightly larger declines in CrCl, of unknown clinical importance, were observed with TDF use over time.
Risk Factors for Atazanavir (ATV)-Associated Urolithiasis: A Case-Control Study

Barbara De Sousa¹, Diane Ponscarme¹, Nathanael Lapidus², Michel Daudon³, Laurence Weiss⁴, Christophe Rioux⁵, Erwan Fourni⁶, Christine Katlama⁷, Jean-Michel Molina⁸, Matthieu Lafaurie¹

Background: Urolithiasis have been reported in patients treated with ATV. Risk factors, clinical features and outcome of ATV-associated urolithiasis have not been fully investigated.

Methodology: From January 2008 to December 2012, we collected all cases of ATV-associated urolithiasis among HIV-infected patients receiving ATV-containing regimens in Paris. A case-control study was then performed with cases defined as adults in whom an ATV-containing urolithiasis had been identified by spectroscopic analysis. Three controls per case were randomly selected among patients treated with ATV-based regimens for at least 6 months and no history of ATV-associated urolithiasis. Patients characteristics, treatment and outcome were retrieved from medical charts at diagnosis and 6-12 months later. An univariate logistic regression analysis was carried out to identify factors associated with the occurrence of ATV-containing urolithiasis and all factors with p-value < 0.20 were kept for a multivariate model selection.

Results: Thirty cases were analyzed. Patients were mostly men (87%), with a median age of 45.5 years, a median CD4 cell count of 443 cells/μL. 97% had plasma HIV RNA levels < 50 cp/mL. Median time between the initiation of ATV-containing regimen and the diagnosis of urolithiasis was 3.1 years [IQR: 2.2-3.8]. Clinical symptoms leading to diagnosis were flank pain in 90% and hematuria in 63%. At diagnosis, renal failure (MDRD creatinine clearance <60 mL/min) was reported in 16/30 (53%) of patients. Ureteroscopic treatment was required in 48% (14/29) of patients and a double J catheter was left in place in 29% (8/28) of cases. 6-12 months after the episode, creatinine clearance remained < 60 mL/min in 5/13 (38.5%) patients. Factors associated with urolithiasis in the univariate analysis were a history of urinary lithiasis (OR=6.86 (95% CI=2.35, 20.03), p<0.001), the use of ritonavir as ATV-booster (OR=9.38 (95% CI: 1.21, 72.9), p<0.04), previous indinavir use (OR 3.25 (95%CI: 1.33, 7.96), p<0.01), duration of exposure to ATV (OR=1.37 per year (95% CI=1.04, 1.79), p<0.03) and serum bilirubin levels (OR=2.08 per 2-fold increase (95% CI=1.19, 3.61), p<0.01). The final
multivariate model identified serum bilirubin (OR=2.66 per 2-fold increase (95% CI=1.35, 5.21), p<0.01) and duration of exposure to ATV (OR=1.42 per year (95% CI=1.04, 1.93), p<0.03) as independent risk factors.

**Conclusions:** Although rare, ATV-containing urolithiasis can be associated with severe renal dysfunction and may require surgical treatment. A high serum bilirubin level and long exposure to ATV-containing regimens are independent risk factors for this complication.

**796 Single Nucleotide Polymorphisms in UGT1A1 Associate With Atazanavir-Related Nephrolithiasis**

**Takeshi Nishijama, Kiyo Tochigi, Akane Joya, Yohel Hamada, Jumie Tanuma, Kunihisa Tsukada, Katsuji Teruya, Yoshimi Kikuchi, Shinichi Oka, Hitoshi Uda, Akihiko Sakai, Hitoshi Kojima, Kiyoto Tsuchiya, Akane Joya, Yohei Hamada, Junko Tanuma, Kunihisa Tsukada, Katsuji Teruya, Yoshimi Kikuchi, Shinichi Oka, Hiroyuki Gatanaga AIDS Clinical Center, National Center for Global Health and Medicine, Tokyo, Japan**

**Background:** Ritonavir-boosted atazanavir (ATV/r) is a widely used antiretroviral drug though it can cause nephrolithiasis. The aim of this study was to determine the association between polymorphisms in genes encoding proteins that take part in metabolizing process of ATV and drug transporters, and ATV/r-associated nephrolithiasis in HIV-1-infected patients treated with ATV/r.

**Methodology:** The 20 single nucleotide polymorphisms (SNP) in the ABCB1, NR1I2, UGT1A1, SLC01B1, and CYP3A5 genes were examined in case patients with ATV/r-induced nephrolithiasis (n=31) and controls (n=47). Case patients were those with a clinical diagnosis of nephrolithiasis while on ATV/r, based on new onset of acute flank pain plus one of the following: 1) new-onset hematuria, 2) documented presence of stones by either abdominal ultrasonography or computed tomography, 3) confirmed stone passage. Control patients were consecutively enrolled among those with >2 years of ATV/r experience in whom nephrolithiasis did not occur. Genotyping was performed by allelic discrimination using TaqMan 5'-nuclease assays with standard protocols. Associations between alleles and ATV/r-associated nephrolithiasis were tested by univariate and multivariable logistic regression analyses.

**Results:** None of patient characteristics variables (sex, age, body weight, body mass index, CD4 count, renal function, serum uric acid, co-administration of tenofovir, history of nephrolithiasis and indinavir use) was associated with ATV/r-associated nephrolithiasis. Multivariate analyses adjusted with sex and age showed a significant association between ATV/r-associated nephrolithiasis and three SNPs located in the shared UGT1A1-3'UTR region: any G allele at position 339 (rs1042640, adjusted OR=5.704; 95% CI, 1.592-20.44; p=0.008), any G allele at position 440 (rs8330, adjusted OR=5.704; 95% CI, 1.592-20.44; p=0.008), and any T allele at position *211 (rs10929303, adjusted OR=3.660; 95% CI, 1.163-11.52; p=0.027). The distribution of all other SNPs, including the UGT1A1*28 allele was not different between case and control patients.

**Conclusions:** This is the first study to identify the association between SNPs in UGT1A1 and atazanavir-associated nephrolithiasis. Atazanavir-treated patients with these SNPs might be at higher risk of atazanavir-associated nephrolithiasis than those without.

**797 Atazanavir and Tenofovir Attenuate the Benefit of Antiretroviral Therapy On Cystatin C: ACTG A5224**

**Chris T. Longenecker1, 2, Douglas Fitch3, Paul Sax4, 5, Eric Daar6, 7, Camlin Tierney8, Grace A. McComsey1, 2**

1Case Western Reserve University School of Medicine, Cleveland, OH, United States, 2University Hospitals Case Medical Center, Cleveland, OH, United States, 3Harvard School of Public Health, Boston, MA, United States, 4Harvard Medical School, Boston, MA, United States, 5Brigham and Women’s Hospital, Boston, MA, United States, 6Los Angeles Biomedical Research Institute, Torrance, CA, United States, 7David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, United States

**Background:** Plasma cystatin C is a biomarker of kidney function thought to more accurately reflect glomerular filtration rate (GFR) than serum creatinine. Whether inflammation affects cystatin C concentrations is controversial. The differential effects of antiretroviral therapy (ART) on cystatin C are poorly understood.

**Methodology:** ACTG A5224s was a substudy of A5202 which randomly assigned 1857 ART-naive HIV-infected adults to blinded abacavir/lamivudine (ABC/3TC) or tenofovir/emtricitabine (TDF/FTC) with open-label efavirenz (EFV) or atazanavir/ritonavir (ATV/r). The factorial design was analyzed with one- and two-sample t-tests and multivariable linear regression was used to analyze changes in plasma cystatin C from 0 to 96 weeks. Spearman correlations were used to analyze baseline and change relationships between cystatin C and biomarkers of inflammation.

**Results:** Of 269 substudy participants, 85% were male and 66% White non-Hispanics; baseline mean (standard deviation) CD4 count was 236(165) cells/mm3 and cystatin C level 0.89(0.17) mg/L. On average, cystatin C decreased significantly over 96 weeks within each arm (p<0.003). ATV/r and TDF/FTC use were each associated with significant or marginally significant attenuation of the beneficial effects of ART on cystatin C (Figure, no evidence of treatment interaction). In a multivariable regression model, higher baseline HIV-1 RNA, assignment to ABC/3TC, and to EFV were independently associated (p<0.05) with greater % decrease in cystatin C. At baseline, cystatin C was positively correlated with biomarkers of inflammation and endothelial activation: high sensitivity C-reactive protein (r=0.25), interleukin-6 (r=0.34), soluble intercellular adhesion molecule (r=0.36), soluble vascular cell adhesion molecule (r=0.54), tumor necrosis factor-α (r=0.57), and soluble TNF-α receptor-I (r=0.70, all p<0.001). Reductions in cystatin C from 0 to 96 weeks correlated with reductions in inflammatory biomarkers (r=0.39 to 0.58, p<0.001) except for hsCRP (r=0.89) and IL-6 (r=0.24).
Conclusions: The beneficial effect of initiating ART on kidney function as measured by plasma cystatin C levels is attenuated by boosted ATV and TDF/FTC when compared to EFV and ABC/3TC containing regimens, respectively. Decreases in plasma cystatin C after ART initiation may result from improved GFR, but may also be due to decreased systemic inflammation.

Figure: Mean (95% CI) percentage change in plasma cystatin C concentration from 0-96 weeks by treatment group. The intention to treat analysis is displayed below the graphs (p value for between-group difference).

A Chronic Kidney Disease Risk Score To Determine Tenofovir Safety Among HIV+ Male Veterans
Rebecca Scherzer1, Monica Gandhi1, Michelle Estrella2, Phyllis Tien1, Steven Deeks1, Carl Grunfeld1, Carmen Peralta1, Michael Shlipak1
1University of California San Francisco, San Francisco, CA, United States, 2Johns Hopkins University, Baltimore, MD, United States

Background: Tenofovir disoproxil fumarate is a widely used antiretroviral for HIV infection that has been associated with an increased risk of chronic kidney disease (CKD). Our objective was to derive a scoring system to predict 5-year risk of developing CKD in HIV-infected adults, and to estimate differences in risk associated with the use of tenofovir.

Methodology: 21,590 HIV-infected men from the Veterans Health Administration aged 18 to 86 years (mean age 47; 54% black) who initiated antiretroviral therapy from 1997-2010 contributed 193,771 years of follow-up. Our outcome was time to first occurrence of CKD, defined as estimated glomerular filtration rate <60ml/min/1.73m2. We developed a point-based score (the VA HIV CKD, or “VHC” risk score) using multivariable Cox proportional hazards models, with weighted point values assigned using regression coefficients from the model.

Figure: Five-year CKD risk by number of VHC points among tenofovir ever and never users
We assessed traditional kidney risk factors and HIV-related factors for CKD, using stepwise backward selection (significance level of \( \alpha = 0.05 \)) to remove candidate covariates.

**Results:** Median follow-up was 6.3 years, during which 2,059 CKD events occurred. The dominant contributors to the VHC risk score were traditional kidney risk factors (age, glucose, systolic blood pressure, hypertension, triglycerides, proteinuria), although CD4 cell count was also a component. HIV RNA levels were not associated with increased CKD risk in the final model. The overall 5-year event rate was 7.7% in tenofovir users and 3.8% in non-users (adjusted HR=2.0, 95%CI: 1.8-2.2). The VHC Cox model identified a progressive increase in the risk of CKD, with 5-year risks in non-users of tenofovir ranging from <1% (0 points) to 16% (≥9 points), and risks from 1.4% to 21.4% among tenofovir users. Although hazard ratios for tenofovir were higher in those with fewer points (HR=2.8 for 0 points, HR=1.3 for ≥9 points), absolute risk and number needed to harm were worst in those with greater points (NNH=108 for zero points, 20 for ≥9 points). Longer tenofovir exposure was associated with a higher overall 5-year CKD event rate (11.1% for 2 years vs. 6.3% for <2 year of exposure), resulting in an NNH of 6 in those with ≥2 years and ≥8 points.

**Conclusions:** The VHC risk score can be used to predict an HIV-infected individual’s absolute risk of developing CKD over five years, and may facilitate clinical decision making around tenofovir use.

### 799 Genetic Variants of ABCC2 and ABCC10 Are Associated With TFV-Induced Proximal Tubular Dysfunction

**Anchalee Avihingsanon**1, Baralee Punyawudho2, Kerkiat Praditpornsila4, Yingyos Avihingsanond1, Wirach Maek-a-nantwatt,1, Jiratchaya Sophonphand1, Sasiwimol Uboyan3, Stephen Kerr1, 3, David Burger3, Kiat Ruxrungtham2, 4, and HIV-NAT 114 study team

**1**HIV-NAT, TRCARC, Bangkok, Thailand, **2**Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, **3**Faculty of Pharmaceutical Sciences, Bangkok, Thailand, **4**Division of Nephrology, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, **5**Kirby Institute, University of New South Wales, Sydney, Australia, **6**Radboud University Nijmegen Medical Center, Nijmegen, Netherlands, **7**Medicine, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand

**Background:** Tenofovir (TFV) is an effective and widely used treatment for both HIV and hepatitis B virus infection. However, it’s use in some patients leads to proximal renal tubular dysfunction (PRTD). We aimed to determine the association between polymorphisms in genes encoding drug transporters and PRTD in Thai patients treated with TFV.

**Methodology:** PRTD was defined as the presence of at least 2 of the following: phosphaturia (total excretion of phosphate >1200 mg per day), or renal tubular reabsorption of phosphate (TmP/GFR) <2.6 mg/dL, uricosuria (FE of uric acid >15%), or non-diabetic glucosuria (urine glucose >300 mg per day or positive urine glucose with plasma glucose <120 mg/dL). Nine single nucleotide polymorphism (SNPs) in the ABCC2, ABCC4, ABCC10, and SCL22A6 genes were determined in 358 Thais taking TFV-based antiretroviral regimens. Genotypes were determined by allelic discrimination using the Tagman 5′-nuclease assay. Associations between genotypes, subject demographic, disease and treatment characteristics and PRTD were analysed by univariate and stepwise multivariate logistic regression.

**Results:** Of 358, 67 (18.7%) patients met the criteria of PRTD. After adjusting for age and a history of diabetes, multivariate analysis demonstrated a significant association between PRTD and genotype CC at position 24 (adjusted odds ratio [OR] 2.38, 95% confidence interval [CI] 1.28-4.45, P=0.006); genotype GG at position 1249 (OR 2.72, 95%CI 1.38, 5.37, P=0.009) and genotype CC or CT at position 2759 (OR 2.56, 95%CI 1.26-5.21, P=0.009). We found a significant association between SNPs in ABCC2 and ABCC10 and TFV-induced proximal tubular dysfunction in an Asian population. Pharmacogenetic factors may play a role in the risk of renal toxicity associated with the use of TFV. Close monitoring of renal function is warranted in TFV-treated patients with these SNPs.

### 800 End-Stage Kidney Disease and Kidney Dysfunction in HIV-Positive Patients

**Esther N. Gathogo**1, Sophie Jose2, John Booth3, Stephen P. McAido1, Emil A. Kumar4, Michael Raymont1, Clifford Leen1, Deborah Williams1, Caroline Sabin5, Frank Post1

1Renal Sciences, King’s College London, London, United Kingdom, 2University College London, London, United Kingdom, 3Imperial College London, London, United Kingdom, 4Chelsea and Westminster Hospital, London, United Kingdom, 5Western General Hospital, Edinburgh, United Kingdom, 6Brighton and Sussex University Hospitals, Brighton, United Kingdom

**Background:** HIV positive individuals are at increased risk of end-stage kidney disease (ESKD). We describe the clinical epidemiology and outcomes of HIV/ESKD in the UK CHIC Study including eligibility for and use of kidney transplantation (KT).

**Methodology:** Observational cohort study of patients in UK CHIC who received permanent renal replacement therapy between 01/2000 and 12/2011, with follow up to 12/2012. Cases were identified by review of all patients with stage 5 chronic kidney disease and by searching local renal databases. ESKD incidence and prevalence rates were calculated, Poisson regression was used to identify factors associated with ESKD, Kaplan-Meier methods to estimate survival rates, and the log rank test to compare survival curves.

**Results:** Of 27817 patients, 112 (0.4%); median age 38 years, male 69%, black ethnicity 64%, HIV-associated nephropathy 46%, median eGFR at baseline 22 mL/min/1.73m² had a diagnosis of ESKD. Throughout the 12 year study period, the ESKD incidence remained stable at 1.12 (95%CI 0.80, 1.44) and 0.23 (0.15, 0.31) per 1000 person-years of follow up for patients of black and non-black ethnicity respectively. The ESKD prevalence increased from 4.4% in 2000/2001 to 10.7% in 2010/2011 among black individuals (p<0.01) and remained stable around 1.8% for non-black ethnicities (p=0.78). Factors associated with ESKD in multivariable analysis were: black ethnicity (HR 2.72 [95%CI 1.38, 5.37]), age (1.42 [1.12, 1.81] per 10 years), CD4 cell count (0.93 [0.88, 0.99] per 50 cells increase), HIV load (0.44 [0.23, 0.84] per log10 copies/mL), hepatitis B (2.73 [1.27, 5.86]) and hepatitis C (2.50 [1.09, 5.77]) co-infection. From 2005 onwards, kidney transplantation (KT) was increasingly used to treat ESKD so that by 12/2012, of the 71 patients still alive and under follow up, 31 (44%) were post-KT, 27 (38%) were being worked up or awaiting KT (pre-KT), and 13 (18%) were permanently unsuitable for KT. During this period, the one and five year survival estimates were similar for patients pre-KT and post-KT (100% and 94% at one year, and 89% and 85% at five years respectively, p=0.53), while survival for those unsuitable for KT was substantially worse (83% and 46% at one and five years, p<0.0001).
Conclusions: In the era of combination antiretroviral therapy, the incidence of ESKD has remained stable while the prevalence in black patients continues to increase. Low mortality was observed among patients with ESKD who were eligible for transplantation irrespective of whether they were maintained on dialysis or successfully transplanted. As the majority of patients have advanced kidney disease at the time of HIV diagnosis, ESKD prevention strategies should include efforts to diagnose HIV infection earlier, especially in those of black ethnicity.

**Obesity: ART and Animal Models**

**801**  
**Maraviroc, a CCR5 Antagonist, Alters Gut Microbiota Composition in a Mouse Model of Obesity**  
*Patricia Pérez-Matute*, Laura Pérez-Martinez*, Jose R. Blanco*, Jose A. Oteo  
*‘Infectious Diseases, CIBIR, Logroño, Spain, 2Infectious Diseases, Hospital San Pedro-CIBIR, Logroño, Spain*

**Background:** Changes in intestinal microbiota, through their effects on energy homeostasis and inflammation, could contribute to the development of several pathologies. Preservation of gut microbiota composition arises as a promising tool to prevent the development of different disorders such as obesity. Maraviroc (MVC), a CCR5 antagonist approved for the treatment of HIV-infected patients, has shown neutral or even beneficial effects on liver and adipocyte metabolism, suggesting beneficial actions in overweight/obese HIV-infected patients. However, MVC impacts on gut microbiota have not been analyzed yet. The aim of this study was to investigate the effects of MVC on gut microbiota composition in a mouse model of obesity.

**Methodology:** A total of 32 male C57BL/6 mice were randomly assigned to one of the following groups: a) Control group (chow diet), b) MVC group (chow diet plus 300 mg/L MVC in the drinking water) c) High-fat diet group (HFD) or d) HFD+MVC group. Body weight and food intake was recorded every 2-3 days. All mice were euthanized after 16 weeks of treatment and cecal contents were removed to study gut microbiota composition. We analyzed by real time PCR four orders from the most dominant phyla in gut.

**Results:** As expected, HFD induced a significant increase in body weight gain (p<0.001). MVC showed a tendency to decrease this body weight gain despite the HFD (p=0.06). Mice fed with a HFD showed a significant increase in the expression of Enterobacteriaceae in comparison with the controls (p<0.001). MVC treatment induced a significant decrease in the mRNA levels of this order in both control and HFD mice (p<0.001). HFD induced a significant decrease in Bacteroidiaceae and Clostridiaceae mRNA levels (p<0.05 and p<0.001 respectively). MVC decreased the expression of Bacteroidiaceae in the group of animals fed with a control diet (p<0.05) while a tendency to increase the expression of this order was observed in HFD mice (p=0.05). No direct effects were observed on the Clostridiaceae after MVC supplementation, although a slightly decrease was observed in HFD mice. Finally, HFD significantly increased the mRNA levels of Lactobacillales (p<0.05) while no significant effects were observed after MVC supplementation, although a tendency to decrease the expression levels of this order was observed in HFD mice.

**Conclusions:** This is the first study that demonstrates the ability of MVC to modify gut microbiota composition. Whether the changes in gut microbiota induced by MVC are associated with the lower body weight gain observed, is still unknown. Our results suggest that some MVC actions seem to be dependent on diet composition and the metabolic status of animals. If these facts should be taken into account when we design antiretroviral regimens must be further investigated.

**802**  
**Low Pre-ART CD4+ T Cells, Female Sex, and Atazanavir Use Increase Obesity Risk After Starting ART**  
*Benjamin Atkinson*, Supriya Krishnan, Ann C. Collier*  
*1Harborview Medical Center, Seattle, WA, United States, 2Statistical and Data Analysis Center, Harvard School of Public Health, Boston, MA, United States, 3University of Washington School of Medicine, Seattle, WA, United States*

**Background:** Obesity prevalence in the United States has increased in recent years. Obesity increases the risk for metabolic diseases and conflicting data exist about the relationship between higher body mass index (BMI) and CD4+ T-cell responses to antiretroviral therapy (ART).

**Methodology:** We evaluated the incidence and risk factors for development of obesity in >3000 ART-treated HIV-infected adults initiating combination ART in randomized AIDS Clinical Trials Group (ACTG) studies who were followed long-term with standardized evaluations as part of the ACTG Longitudinal Linked Randomized Trials (ALLRT) cohort. Cox regression models were used to examine baseline factors and randomized ART associated with incident obesity (BMI ≥30 kg/m²) after starting ART.

**Results:** 2900 participants with pre-ART BMI <30 kg/m² were followed a median of 4.3 years (Q1, Q3: 2.1, 7.4) after starting ART. Subjects were excluded for missing baseline BMI values (N=11) and pre-ART BMI ≥30 kg/m² (N=475). Subjects were 85% male, 45% non-Hispanic white, and had median pre-ART age of 38 years, pre-ART CD4+ T-cells of 211 cells/μL and HIV RNA of 4.8 log_{10} copies/mL. Median pre-ART BMI was 23.8 kg/m² (Q1, Q3=21.6, 26.1) in males and 24.1 kg/m² (21.3, 26.3) in females. A total of 645 (22%) subjects developed obesity. In univariate and multivariable models, female sex (Hazard Ratio [HR]=1.88, 95% Confidence Interval [CI]=1.56-2.27), and pre-ART BMI 25-≥30 kg/m² (HR=7.66, 95% CI=6.35-9.23 relative to BMI 18.5-<25 kg/m²) and pre-ART CD4+ T-cells ≥50 (hazard ratio HR=3.21, 95% CI=2.27-4.54 relative to CD4 >500) and 51-200 (HR=2.12, 95% CI=1.52-2.98 relative to CD4 >500) were significantly associated with an increased risk of obesity (all p<0.0001). In multivariate analyses that included baseline age, sex, race, BMI, and CD4+ T-cells, use of atazanavir (N=521) was associated with an increased risk of incident obesity (HR=1.29, 95% CI=1.01-1.64) versus non-protease inhibitor (PI)-containing regimens (N=1527) (p<0.04). Neither stavudine or zidovudine use was associated with obesity risk in multivariate analysis, compared to regimens without nucleoside reverse transcriptase inhibitors (HR=0.71, 95% CI=0.43-1.18; and HR=0.76, 95% CI=0.48-1.22; respectively).
Conclusions: Earlier initiation of ART may help reduce the incidence of obesity in ART-treated individuals. Females were at significant risk for obesity in this cohort, suggesting that perhaps they should be targeted for interventions to minimize unhealthy weight gain associated with initial ART use. While atazanavir has previously been reported to minimize dyslipidemia compared to other PIs, an association with greater obesity risk may contribute to poor health outcomes.

803 Obesity or Hypertension at ART Initiation and Outcomes Amongst HIV Patients in South Africa
Alana T. Brennan1,2, Matthew P. Fox1,2, Mhairi Maskew2, Ian Sanne1,2, Prudence le1,2, Julia Rohr1,2, Lawrence Long1,2, Sydney Rosen1,2
1Center for Global Health & Development, Boston University, Boston, MA, United States, 2Department of Internal Medicine, School of Clinical Medicine, Faculty of Health Sciences, Health Economics and Epidemiology Research Office, Johannesburg, South Africa, 3Department of Internal Medicine, School of Clinical Medicine, Faculty of Health Sciences, Clinical HIV Research Unit, Johannesburg, South Africa

Background: Aging, antiretroviral therapy (ART) and HIV infection itself have all been associated with increasing rates of chronic comorbidities in HIV patients but there are limited data on chronic disease risk factors and HIV treatment outcomes in resource-limited settings. We evaluated the association between high body mass index (BMI) or hypertension at ART initiation and mortality, loss to follow-up (LTF), and immunological and virologic response among HIV positive patients on treatment in South Africa.

Methodology: Prospective cohort study over 4 years among ART naive adults initiating ART in Johannesburg between April 2004 and July 2009. Cox regression was used to model the association with mortality and LTF of BMI (<18, 18-24.9, 25-29.9 and ≥30kg/m²) and blood pressure (BP) grouped as normal (systolic <140 and diastolic <90 mmHg), mild (systolic 140-159.9 and/or diastolic 90-99.9 mmHg) and moderate/severe (systolic ≥160 and/or diastolic ≥100 mmHg). Linear and log-binomial regression were used to evaluate associations with CD4 increase and viral load ≥400 copies/mL, respectively. For mortality and LTF, person-time started at ART initiation and ended at the earliest of death, LTF, transfer or dataset close (July 2013).

Table 1. Crude and adjusted relative risks of the association between BMI or BP at ART initiation and death, loss to follow-up and mean CD4 change from ART initiation at 12 and 48-months post ART initiation in Johannesburg, South Africa (n=9693)

*All models were adjusted for age and gender and clinical characteristics at ART initiation (CD4 count, hemoglobin, tuberculosis and WHO stage)

**Absolute mean change in CD4 count from ART initiation
Results: 63% of the 9693 patients included were female and the majority (92%) initiated stavudine-lamivudine-efavirenz. At ART initiation median (IQR) CD4 count was 86 cells/mm$^3$ (33-154), BMI 21.4 kg/m$^2$ (19.0-24.5), systolic BP 116 mm/Hg (105-128), and diastolic BP 76 mm/Hg (68-85). By 48 months, 1001 (10%) patients died and 2069 (21%) were LTF. We found patients with a BMI $\geq$30 kg/m$^2$ had an increase in mortality over 48 months on ART compared to patients with a BMI of 18-24.9 kg/m$^2$, but lower LTF and improved immune response during follow-up (Table). We found no association between obesity and having a detectable viral load. Patients with moderate/severe hypertension (vs. normal) had a slight increase in mortality (30-40%) over follow-up but no increase in LTF, CD4 response, or having a detectable viral load.

Conclusions: Chronic disease risk factors at ART initiation may be associated with small increases in mortality but appear to be protective against LTF and poor immunological response. Successful management and treatment of comorbidities, specifically amongst obese patients that present with moderate to severe hypertension, may help decrease mortality in HIV infected patients.

804 Specific Binding Characteristics of HLA Alleles Associate With Nevirapine Hypersensitivity
Rebecca Pavlos1, Craig Rice1, Elizabeth McKinnon1, David Ostrov2, Boem Peters3, Jing Yuan4, Silvana Gaudieri1, 5, David Haas6, Simon Mallal1, 6, Elizabeth J. Phillips1, 4
1Institute for Immunology and Infectious Diseases, Murdoch, Australia, 2University of Florida College of Medicine, Gainesville, FL, United States, 3La Jolla Institute for Allergy and Immunology, La Jolla, CA, United States, 4Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, CT, United States, 5University of Western Australia, Crawley, Australia, 6Vanderbilt University Medical Center, Nashville, TN, United States

Background: Multiple class I and II HLA associations have been described in association with nevirapine (NVP) hypersensitivity reaction (HSR) phenotypes. We tested the hypothesis that peptide binding (PB) properties may be shared between these alleles.

Methodology: HLA-A,-B,-C, -DR typing was performed on stored DNA from a retrospective case controlled analysis of NVP HSR (ClinicalTrials.gov NCT00310843) using the 454 FLX platform. Univariate and multivariate analyses stratified for race were performed according to HLA class I/II alleles, HLA supertypes and HLA alleles according to PB (Sidney J, Lund O). Kir ligand groupings and HLA B/C haplotypes for cutaneous and hepatitis phenotypes of NVP HSR. In silico modelling to simulate HLA binding to NVP was performed with the highest ranked candidates.

Results: HLA-A,-B,-C and -DR typing resolved to four digits (794 samples (controls =524, cutaneous NVP HSR cases =170, hepatitis NVP HSR cases = 100)). Multivariate analysis of cutaneous NVP HSR in Southeast Asians (SEA) associated DR4 supertype (OR=2.9, p=0.015) and alleles with HLA-35/18 PB properties (OR=6.4, p=0.002). HLA-DRB1*01:02 was associated with hepatitis NVP HSR in Caucasians (OR=2.7, p=0.01) whereas carriage of alleles of the PB B46 were protective (OR=0.3, p=0.04). HLA-C*04:01 was associated with cutaneous NVP HSR, including SJ/TS/TEN across all races (p<0.0001, Mantel-Haenszel test; Caucasians: OR=2.8 [1.3-5.9], p=0.009; African Americans: OR=4.0 [1.4-13.0], p=0.02; SEA: OR=9.0 [3.2-24.9], p<0.0001). However, haplotype analysis of HLA-B/C showed pairing of HLA-C*04:01 with HLA-B alleles with B35 and B18 like PB (HLA-B*35:01,B*35:05,B*35:08,B*53:01,B*18:01,B*18:02, B*44:02,B*44:03), and this effect was strongest in SEA where carriage of HLA-C*04:01 when paired with the HLA-B alleles (OR=11.8, p=0.0003) was more strongly associated with cutaneous NVP HSR than HLA-C*04:01 carried alone (OR=4.8, p=0.047). This suggests that risk of cutaneous NVP HSR attributed to carriage of HLA-C*04:01 may be enhanced by HLA-B alleles which are in strong linkage disequilibrium. An in silico and peptide binding model both suggest that NVP non-covalently binds in the F pocket of HLA-B*35:05 and near the B pocket of HLA-C*04:01. In multivariate analyses, Kir ligand groupings Bw4/Bw6 and C1/C2 did not significantly contribute to the modelling of associations with cutaneous hypersensitivity or hepatitis.

Conclusions: Cutaneous and hepatitis phenotypes of NVP HSR associate with different HLA-B and DR-alleles respectively that share PB characteristics. The pairing of these HLA-B alleles with HLA-C*04:01 appears important for the development of cutaneous NVP HSR, providing a testable model for the immunopathogenesis of NVP HSR.

805 Large-Scale Gene-Centric Exploration of Risk for NRTI/NNRTI-Associated Toxicities in Botswana
C. William Wester1, 2, Sophie Limou3, Hermann Bussmann4, 5, Vladimir Novitsky1, 4, Sikululile Moyo6, Max Essex2, 4, Richard G. Marlink4, 4, Cheryl A. Winkler1
1Vanderbilt Institute for Global Health (VIGH), Vanderbilt University School of Medicine, Division of Infectious Diseases, Nashville, TN, United States, 2Department of Immunology and Infectious Diseases, Harvard School of Public Health, Boston, MA, United States, 3Center for Cancer Research, Basic Science Program, Frederick National Laboratory, Lexicon BioMedical Research for the National Cancer Institute, Frederick, MD, United States, 4Botswana-Harvard School of Public Health AIDS Initiative Partnership for HIV Research and Education (BHP), Gaborone, Botswana

Background: Access to combination antiretroviral therapy (ART) in sub-Saharan Africa (SSA) has expanded due to a large number of national initiatives. Previous studies have shown higher rates of NRTI and NNRTI-related toxicity when comparing patients on ART in SSA with those in resource-replete settings. The Tshepo study is the first to extensively evaluate the association of host genetic factors on ART-related toxicity heterogeneity in SSA.

Methodology: The Tshepo study is a 3-year randomized clinical study following 650 ART-naïve adults (69.4% female) from Botswana who initiated first-line NNRTI-based ART. We conducted a large-scale gene-centric association study on Tshepo participants with sufficient DNA using the Illumina Human CardioMetabolo Beadchips enriched in markers for metabolic and cardiovascular genes (198K), including mitochondrial, ADME, renal, and immune response genes. After quality control, 133,822 SNPs were tested for association with 5 NRTI/NNRTI-associated toxicities in 568 individuals. Of these, 62 had peripheral neuropathy (PN), 20 had NVP-associated hypersensitivity cutaneous reaction (NS), 19 had ZDV-related anemia (ZA), 19 had pancreatitis (PA), and 17 had moderate-severe hyperlactatemia/lactic acidosis (LA). Logistic regressions in an additive model were performed and adjusted for gender, age, CD4, plasma HIV-RNA level, and BMI at baseline, as well as for the first two eigenvectors from the population stratification analysis.
Results: Although no SNP reached the Bonferroni study-wide significance level (P<3.7x10^-7), several SNPs met the suggestive significance threshold (P<10^-5): rs2503875 (chr10, OR=7, P=5x10^-7) and rs7767230 (chr6, OR=9, P=2x10^-6) for PN; rs702864 (chr21, OR=6, P=7x10^-6), rs2902211 and rs11589503 (chr1, OR=5-6, P=9x10^-6) for NS; three chr6 markers (OR=9-10, P=4-7x10^-6), and two chr18 markers (OR=9-11, P=5-9x10^-6) for PA.

Conclusions: This first large genetic study to evaluate ART-associated toxicity in Africa revealed putative candidate loci for several potentially life-threatening and/or debilitating NRTI/NNRTI-related toxicities with robust effect sizes. These preliminary findings warrant validation and further investigation.

Figure 1: Manhattan plot. Distribution along the chromosomes of -log_{10}(P-value) obtained in each of the 5 NRTI/NNRTI-related toxicities association studies. The red line marks the Bonferroni study-wide significance threshold (P=3.7x10^-7), and the blue line marks the suggestive significance threshold (P=10^-5). PN=Peripheral neuropathy, and NS=NVP-associated hypersensitivity cutaneous reaction.

760  Suicide Rates Decrease Among HAART Initiators From 1996 To 2012 in British Columbia, Canada
Silvia Guillemi1,2, Erin Ding1, Jasmine Gunn1, Julia Zhu1, Verena Strehlau1, Julio S. G. Montaner1,2, Robert S. Hogg1,4
1BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 2University of British Columbia, Faculty of Medicine, Vancouver, BC, Canada, 3University of British Columbia, Department of Psychiatry, Vancouver, BC, Canada, 4Simon Fraser University, Faculty of Health Sciences, Burnaby, BC, Canada

Background: Suicide rates among people living with HIV/AIDS (PLHIV) have been reported at markedly higher levels than in the general population. We sought to evaluate this trend and identify factors associated with suicide among PLHIV who have initiated Highly Active Antiretroviral Therapy (HAART) in British Columbia (BC), Canada.

Methodology: Our analysis was based on all treatment naive individuals who initiated HAART in BC from August 1996 to June 2012. Data on deaths were ascertained from monthly linkages with the BC Vital Statistics Registry. Logistic regression and Cox Proportional hazard models were used to identify factors independently associated with suicide mortality. Suicide was defined by any of the following ICD-10 “cause of death” codes: E850-E854, E858, E862, E868; X40-X42, X46, X47; Y10-Y12, Y16, Y17; E950-E952, X60-X69; E953, X70; E954, X71; E955, X72-X75; E958.1, E958.2; X76, X77, E956, X78, X79; E957, X80; E958.0, X81; E958.5, X82; E958.3, E958.4, E958.5, X82; E958.3, E958.4,
E958.6-E958.9; X83, X84. The variables assessed included: gender, Aboriginal identity, median income, urban versus rural neighborhood, age at death and year of death, ever having been diagnosed with an AIDS-defining illness, ever having had a positive hepatitis C (HCV) diagnosis, HAART adherence in the most recent year, most recent HAART cocktail, number of years on HAART, most recent and nadir CD4, most recent viral load, and history of injection drug use.

Results: Among 5,229 PLHIV who initiated HAART over the study period, 993 (19%) died, of which 82 (8.2%) were from suicide. In 1998, suicide mortality peaked at 961 deaths per 100,000 person-years, a rate 91-fold greater than in the BC population, and then declined to 28 deaths per 100,000 person years in 2010, a rate 3-fold greater than the BC population. No deaths from suicide were reported in 2011, which was the last full year of data for the cohort. The Cox model, which included those who committed suicide and those who remained alive at the end of the study period (n = 4318), showed that a history of injection drug use (Adjusted Hazard Ratio [AHR] = 3.95; 95% CI: 1.99-7.86) and never having been diagnosed with an AIDS defining illness (AHR = 4.45; 95% CI: 1.62 - 12.25) were independently associated with time to suicide.

Conclusions: Rates of deaths from suicide declined significantly over the study period. While factors directly related to HIV infection, or type of HAART regimen, were not associated with suicide, other factors related to lifestyle issues, like injection drug use, were.

### 761 Disproportionality Analysis of Antiretrovirals With Suicidality Using FDA AERS Data

Andrew Napoli1, John Coumbis2, Jennifer Wood2, Amit Soitkar2, Daniel Seekins1
1Bristol-Myers Squibb, Plainsboro, NJ, United States; 2Bristol-Myers Squibb, Hopewell, NJ, United States

**Background:** An analysis of 4 ACTG studies, including 5332 subjects, identified an increase in the hazard of suicidality in efavirenz containing regimens compared to regimens containing atazanavir, atazanavir/ritonavir, lopinavir/ritonavir and zidovudine/lamivudine/abacavir. Rare but serious psychiatric adverse events (AEs), including suicide, have been included in postmarketing reports with efavirenz. We conducted a Multi-Item Gamma Poisson Shrinker (MGPS) disproportionality analysis based on data in the FDA Adverse Event Reporting System (AERS) database to assess the potential association of selected antiretrovirals (ARVs), including efavirenz, with suicidality. AERS primarily includes spontaneous serious AE reports from consumers and healthcare professionals of varying quality with fewer entries from clinical trials.

**Methodology:** The AERS database (Q3 2012) search included MedDRA preferred terms “completed suicide”, “suicidal ideation”, and “suicide attempt”. In addition to the ARVs, fluoxetine and sertraline, antidepressants with a Black-Box Warning for suicidality, were included as positive controls. The MGPS method can provide a robust estimate of disproportionality measure (reporting above expected frequency) referred to as the EBGM (Empirical Bayesian Geometric Mean) and corresponding 90% confidence interval (EB05, EB95). The threshold for a potential drug-event signal is generally considered to be EB05 ≥2.

**Results:** The database included 29,836 AE reports among patients receiving efavirenz, atazanavir, darunavir, etravirine, nevirapine, and raltegravir, including 437 reports of completed suicide, suicidal ideation, and suicide attempt. Efavirenz and all comparator ARVs did not exceed the threshold for identification of a disproportional signal for suicide, suicidal ideation, and suicide attempt (EB05 Scores ≥2; Table). Fluoxetine and sertraline had EB05 Scores ≥2 for suicide, suicidal ideation, and suicide attempt.

**Conclusions:** This analysis does not show a disproportional signal for suicide, suicidal ideation, and suicide attempt for efavirenz, atazanavir, darunavir, etravirine, nevirapine, and raltegravir. There are limitations to the AERS data, including a lack of certainty that reported adverse events are related to the drug, lack of sufficient detail in the reports, and underreporting of adverse events. Appropriate baseline psychiatric screening and counseling is important when starting patients on any ARV.

High Clonality of \textit{M. tuberculosis} Strains Among MDR-TB Patients in Gauteng, South Africa

Dorothy A. Fallow\textsuperscript{1}, Nicole Kushner\textsuperscript{1}, Amanda Axcell\textsuperscript{1}, Lynsey Stewart-Isherwood\textsuperscript{2}, Pamela Denis\textsuperscript{3}, Francesca Conрадie\textsuperscript{2}, Gerrit Coetzer\textsuperscript{2}, Hendrik Koornhof\textsuperscript{2}, Nazir Ismail\textsuperscript{2}, Gilla Kaplan\textsuperscript{1}

\textsuperscript{1}PHRI, NJMS-Rutgers University, Newark, NJ, United States, \textsuperscript{2}Centre for Tuberculosis, Johannesburg, South Africa, \textsuperscript{3}Department of Clinical Medicine, University of the Witwatersrand, Johannesburg, South Africa

\textbf{Background:} The problem of multidrug and extensively drug resistant tuberculosis (M/XDR-TB) was first highlighted in the 1990's with an outbreak of MDR-TB in New York City, followed a decade later by an XDR-TB outbreak (KZN strain) in Tugela Ferry, South Africa. Both were due to highly clonal, highly resistant strains of \textit{M. tuberculosis} (Mtbc), spread mainly in HIV infected populations. However, the relative contributions to the M/XDR-TB epidemic in South Africa of clonal spread and de novo acquired resistance are unclear. To better understand the dynamics of MDR-TB transmission and resistance amplification in Mtbc, we carried out a cluster analysis of Mtbc strains from patients initiating treatment for MDR-TB at a referral hospital in Gauteng, South Africa.

\textbf{Methodology:} Mtbc isolates from 74 patients were genotyped by IS6110-RFLP and direct DNA sequencing of 9 resistance determining genes: rpoB, katG, mabA-intA, gyrA, gyrB, pncA, tlyA, rpsL, and rrs. Clusters were defined by 2 or more isolates with an identical IS6110-RFLP. Diagnosis of MDR was confirmed by drug susceptibility testing as part of routine clinical management.

\textbf{Results:} Among the 74 patients, 36\% were HIV infected and 29\% had been treated for at least one prior TB episode. The Mtbc isolates represent 17 strain families and 47 IS6110 genotypes, including 11 (15\%) pre-XDR and 1 (1.4\%) XDR, with 54\% overall clustering (40/74). Pre-XDR and XDR are more clustered (10/12, 83\%) than MDR sensu stricto (30/62, 48\%). Isolates from HIV-positive patients trend towards more clustering (17/26, 65\%, \(p=0.223\)) than those from HIV-negative patients (23/47, 49\%). The majority of clustering is accounted for by 4 families (26/40, 65\%) which comprise 47\% of the total Mtbc population analyzed. The largest strain family (14/74 isolates, 19\%) has the KZN genotype and is highly clustered (10/14, 71\%). One pre-XDR isolate is nearly identical to the KZN strain; the other 13 show diverse mutation profiles, as seen in other South African variants, likely due to independent evolutionary trajectories from a less resistant precursor. Our data shows evidence of multiple importations of KZN strains to Gauteng, with further amplification of drug resistance and ongoing transmission in the region. The other 3 highly clustered strains show similar clonal characteristics with evidence of resistance amplification.

\textbf{Conclusions:} MDR-TB is spreading in Gauteng. A few strains of relatively low diversity are predominant in the MDR-TB population and appear to be undergoing resistance amplification. Transmission seems to be responsible for much of the MDR-TB among HIV-positive patients. The KZN strain is circulating in this population and shows evidence of ongoing resistance amplification.

Identifying Location of Recent TB Transmission in Rural Uganda: A Multidisciplinary Approach

Gabriel Chamie\textsuperscript{1}, Bonnie Wandera\textsuperscript{2}, Carina Marquez\textsuperscript{2}, Midori Kato-Maeda\textsuperscript{3}, Moses R. Kamya\textsuperscript{4}, Diane V. Havlir\textsuperscript{5}, Edwin D. Charlebois\textsuperscript{5}

\textsuperscript{1}Division of HIV/AIDS, San Francisco General Hospital, University of California San Francisco, San Francisco, CA, United States, \textsuperscript{2}Makerere University-University of California San Francisco Research Collaboration, Kampala, Uganda, \textsuperscript{3}Division of Pulmonary & Critical Care Medicine, San Francisco General Hospital, University of California San Francisco, San Francisco, CA, United States, \textsuperscript{4}Department of Medicine, School of Medicine, Makerere University College of Health Sciences, Kampala, Uganda, \textsuperscript{5}Center for AIDS Prevention Studies, University of California San Francisco, San Francisco, CA, United States

\textbf{Background:} Given the substantial burden of undiagnosed TB in sub-Saharan Africa, novel active TB case finding strategies are needed. Location-based TB case finding offers a potentially high yield, community-based approach. However, the precise locations of recent TB transmission events occurring in rural African communities are largely unknown.

\textbf{Methodology:} We recruited all adult residents diagnosed with active TB from July 2012 to June 2013 in Tororo, a rural municipality in Uganda. Active TB cases provided names of household and frequent non-household contacts, sites of residence, health care attendance, work and social activities, and two sputum samples. Household members also provided names of frequent non-household contacts. We performed sputum culture using Lowenstein Jensen and BACTEC MGIT, and used spoligotyping of culture positive specimens to identify recently transmitted TB, defined by genotypic clustering. We analyzed social network structure using Gephi, to identify social ties between TB cases. We mapped and geo-coded GPS locations using ArcGIS by site type (home, work, clinic, social), and identified locations of spatial overlap among genotype-clustered cases to determine likely sites of transmission.

</tbody>
</table>
**Results:** Over one year, 70 adults initiated TB treatment in Tororo; 55 (79%) were enrolled. Of 55 TB cases, 31 (56%) were HIV-infected, 42 (76%) were AFB smear-positive, and 36 (65%) were MTB culture positive. Of 17/36 specimens genotyped to date, 11/17 (65%) belonged to three distinct genotypic clusters. None of the clustered cases shared a home. In one genotypic cluster (cluster A) of three HIV+ women, GPS mapping revealed overlapping social sites - two physically adjacent bars, despite no overlap in social networks, work or clinic sites. In a second cluster of six cases (cluster B), GPS mapping revealed that five genotype-matched cases attended the same medical clinic; the one case not attending this clinic resided next door to another case. No shared household, work or clinic sites, or social network ties were observed in cluster B. Social network analysis revealed ties between at least 2 TB cases in 20/55 (36%) cases.

**Conclusions:** Using a combination of molecular epidemiology, and geospatial and social network data, we leveraged TB cases diagnosed in clinics to determine the most likely sites of recent TB transmission across a rural Ugandan community. In this analysis, the majority of active TB cases genotyped suggested recent TB transmission that was linked to specific community locations. Connections identified between genotype-clustered TB cases using this multi-domain approach would not have been found using traditional household contact investigation alone.

**808 Timing of TB Episodes After the End of Isoniazid Preventive Therapy: Reinfection or Reactivation?**

Sabine Hermans¹, Alison Grant¹, Violet Chihota², James Lewis¹, Gavin Churchyard³, Katherine Fielding³
¹Infectious Disease Epidemiology, London School of Hygiene and Tropical Medicine, London, United Kingdom, ²Clinical Research, London School of Hygiene and Tropical Medicine, London, United Kingdom, ³Aurum Institute for Health Research, Johannesburg, South Africa

**Background:** Isoniazid preventive therapy (IPT) reduces tuberculosis (TB) incidence in high risk populations (HIV-positive and negative), but durability of protection is limited in high burden settings. The underlying mechanism (reactivation of persistent latent TB or re-infection) is not well understood. There are few data on long-term TB incidence after IPT discontinuation. This study aimed to investigate the timing of post-IPT TB incidence and its associated risk factors in a high-TB-risk population with high HIV prevalence (estimated at 29%) in sub-Saharan Africa.

**Methodology:** Data from a cluster randomized trial of community-wide IPT among gold mine workers in South Africa (the ‘Thibela TB’ study) were analysed. Participants in the intervention arm who were prescribed isoniazid at least once and who were alive, in the workforce and TB-free 9 months later (corresponding to the intended duration of IPT) were included. TB incidence rates from the end of the intended period of IPT to the end of the follow-up period for the main study were calculated, overall and stratified by follow-up time (per 6 months). Cox regression analysis was used to investigate risk factors for TB incidence and effect modification by follow-up time. A sensitivity analysis used the actual end of IPT (based on prescription dates) as the start of the risk period.

**Results:** 17,446 participants (96% male, mean age 41 years [yrs; standard deviation 9]) were eligible for the analysis. 541 TB cases were diagnosed during 24,037 person-years at risk (pyar), a median follow-up of 1.4 years. The post-IPT TB incidence rate was 2.3/100 pyar (95% confidence interval [CI], 2.1-2.5) and did not vary during follow-up time (0-0.5 yrs: 2.0/100 pyar [95% CI 1.7-2.3], 0.5-1 yrs: 2.4 [95% CI 2.1-2.8], 1-1.5 yrs: 2.5 [95% CI 2.1-3.0] and ≥1.5 yrs: 2.1 [95% CI 1.6-1.5], P-value 0.12). After adjusting for sex, country of origin and ART use, risk factors identified were older age (30-39 versus ≥50 yrs: aHR 2.2 [95% CI 1.9-4.2], 40-49 yrs: aHR 2.8 [95% CI 1.9-4.2], ≥50 yrs: aHR 2.8 [95% CI 1.8-4.2]), underground mining work (aHR 1.8 [95% CI 1.2-2.5]), living in a mining hostel (aHR of non-hostel versus hostel 0.7 [95% CI 0.6-0.9]) and prior TB disease (aHR 1.9 [95% CI 1.5-2.4]). These factors did not vary importantly over time. The results of the sensitivity analysis did not differ.

**Conclusions:** TB incidence rates were constant over time since IPT cessation. The risk factors identified are well known and are associated with both reactivation and re-infection disease. No important effect modification of these factors by time was found. These findings do not allow conclusions regarding the mechanism underlying post-IPT TB incidence.

---

**809 HIV and Tuberculosis in Kenya, 2012-2013: Results From a National Survey**

Agneta Mbithi¹, Anthony Gichangi², Herman Wyenga¹-³, John Williamson², Tom Oluoch², Katherine Robinson², Timothy Kellogg⁴, Andrea A. Kim², William Maina¹, Kevin M. De Cock¹
¹National AIDS and STI Control Programme, Ministry of Health, Nairobi, Kenya, ²Division of Global HIV/AIDS-Kenya, US Centers for Disease Control and Prevention, Nairobi, Kenya, ³Division of Leprosy, Tuberculosis and Lung Diseases, Ministry of Health, Nairobi, Kenya, ⁴Global Health Sciences, University of California San Francisco, San Francisco, CA, United States

**Background:** Co-infection with tuberculosis and HIV remains a major cause of morbidity and mortality in sub-Saharan Africa. The 2ndKenya AIDS Indicator Survey (KAIS 2012) assessed knowledge and experience concerning tuberculosis and HIV at a population level in Kenya, including coverage with treatment services and antiretroviral therapy (ART).

**Methodology:** KAIS 2012 was a national, population-based, cross-sectional household survey among persons aged 18 months to 64 years conducted from October 2012 to February 2013. Information was collected through household questionnaires and blood samples were taken for HIV testing, CD4+ cell counts and HIV viral load testing at a central laboratory. Respondents were offered home-based HIV testing and counseling and if HIV positive, point-of-care CD4+ T-cell count testing, results of which are not reported here. Kenya’s North-Eastern region (HIV prevalence <1%) was excluded because of insecurity. This analysis was restricted to persons aged 15-64 years. Estimates and 95% confidence intervals (CI) were weighted to account for sampling probability and adjusted for survey non response.

**Results:** Overall, 13,720 persons participated in the survey, of whom 84.8% gave blood. The prevalence of HIV infection was 5.6%. Among persons who had heard of tuberculosis (96.7% overall), 2.0% reported having had the disease; 32.1% of those reporting prior tuberculosis were HIV-infected. Prior tuberculosis was reported by 11.6% of HIV-infected persons compared with 1.4% of HIV uninfected persons (odds ratio 9.4; CI 6.6-12.8). HIV and
tuberculosis co-infection was associated with female sex, geographic origin from Nyanza region, and age range 25-49 years. Significantly more HIV-infected persons with than without prior tuberculosis were in HIV care, accessing ART, or both. For treatment-eligible persons aware of their HIV status and in care, over 95% were receiving ART, irrespective of tuberculosis history. However, including HIV-infected persons unaware of their HIV status and thus not in care, overall ART coverage among those treatment-eligible was 73.9% and 73.3%, respectively, for those with and without prior tuberculosis. Persons with prior tuberculosis accounted for 28.8% of all those on ART.

Conclusions: Two percent of Kenyans reported prior tuberculosis, of whom almost a third were HIV-infected; over one tenth of HIV-infected persons reported prior tuberculosis which was likely a major entry point for HIV testing and HIV care. Persons aware of their HIV status and accessing HIV care had >95% uptake of ART if eligible, but >50% of HIV-infected persons in Kenya are still unaware of their status. Efforts must concentrate on increasing knowledge of HIV serostatus and integrating HIV and tuberculosis services for those living with HIV.

TB Screening and Diagnosis

810 Screening for Tuberculosis in HIV-Infected Nigerian Children With a Urinary Antigen Assay
Holly E. Rawizza1,2, Stephen Oguche1, Godwin Imade1, Oche Asibaj1, David Olayeye1, Georgina Odalbo1, Kiko Osinusi1, Isaac Adewole1, Prosper Okenkwo1, Phyllis Kanki2
1Infectious Disease, Brigham & Women’s Hospital, Boston, MA, United States; 2Harvard School of Public Health, Boston, MA, United States

Background: Tuberculosis (TB) remains the leading cause of death among HIV-infected children in sub-Saharan Africa. Accurate and prompt identification of TB infection remains challenging, particularly among young children who are often unable to produce sputum. In this study, we evaluated the sensitivity and specificity of the lipoproteinmannan (LAM) TB ELISA for the detection of mycobacteria-specific antigen in urine samples of HIV-infected Nigerian children.

Methodology: As part of routine care, all HIV-infected children enrolling in the APIN/Harvard PEPFAR program undergo routine screening for TB consisting of: clinical evaluation for symptoms or signs of TB infection, chest radiograph, and tuberculin skin testing (TST). In addition, for those children with a chronic productive cough, sputum samples are collected when possible. A composite of these standard TB diagnostic techniques was used as the “gold standard”, and compared against results of the urine LAM assay.

Results: 184 HIV-infected pediatric patients were enrolled at two study sites; 40% were female with a median age of 5 years and median baseline CD4+ cell count of 434 cells/mm3. Almost 36% of patients (66 children) were diagnosed with TB within 3 months after collecting the LAM sample. The sensitivity of the LAM assay to detect the composite diagnosis of TB infection is 10.6% (95% CI 4.7-21.2%), specificity is 97.4% (95% CI 91.9-99.3%), and the PPV is 70% (95% CI 35.3-91.9%). The median CD4 count was 103 cells/mm3 (IQR, 25-331 cells/mm3) among children with a positive LAM, compared to 393 cells/mm3 (IQR, 177-717 cells/mm3) among those diagnosed with TB but with a negative LAM result.

Conclusions: Although the sensitivity of the LAM assay was low in this population, the relatively high PPV suggests that a positive result may add valuable information to the care of a sick child. However, more sensitive rapid diagnostic methods for the detection of TB in young children are urgently needed.

811LB Massive Diagnostic Yield of HIV-Associated Tuberculosis Using Rapid Urine Assays in South Africa
Stephen D. Lawn1, Andrew Kerckhoff2, Rosie Burton3, Charlotte Schutz1, Gavin van Wyk4, Monica Vogt4, Pearl Pahlana5, Mark Nicol6, Graeme Meintjes1
1Department of Clinical Research, London School of Hygiene & Tropical Medicine, London, United Kingdom, 2University of Cape Town, Cape Town, South Africa, 3Department of Medicine, University of Cape Town, Cape Town, South Africa, 4Department of Clinical Research, University of Cape Town, Cape Town, South Africa, 5Desmond Tutu HIV Centre, University of Cape Town, Cape Town, South Africa

Background: Autopsy studies of HIV/AIDS deaths in medical in-patients in sub-Saharan Africa have all reported a high frequency of disseminated tuberculosis (TB), indicating frequent failure of diagnosis. This observational study aimed to identify improved means of rapid TB diagnosis.

Methodology: Unselected HIV-infected medical admissions to a South African district hospital were intensively investigated. Sputum, urine and blood specimens were systematically obtained within the first 24 hours. Multiple additional respiratory and non-respiratory samples were obtained throughout admission as clinically indicated. Sputum samples were tested using fluorescence microscopy, liquid culture and Xpert MTB/RIF (Xpert). Urine samples were tested using Xpert (urine-Xpert of both unconcentrated and concentrated samples) and Determine TB-LAM (urine-LAM). Other non-respiratory samples were cultured. TB diagnoses were defined by detection of Mycobacterium tuberculosis in any sample using culture or Xpert.

Results: HIV-status was ascertained in 1,013 of 1,018 (99.5%) admissions and 585 of 609 (96.1%) HIV-infected patients were enrolled. All those without an existing TB diagnosis (n=427) were included in this analysis. 3,471 TB investigations were done on 1,745 samples from a median of 3 anatomic sites per patient. TB was diagnosed in 139 patients (median CD4 count, 80 cells/μL) and symptoms were very poorly predictive. TB prevalence was 32.6% (95%CI, 28.1-37.2). Disease was extrapulmonary in 83% of cases and pulmonary in just 54% (P<0.001). Using samples obtained in the first 24-hours, the proportions of final diagnoses made by sputum microscopy, sputum-Xpert, urine-LAM and urine-Xpert (30-40 ml concentrated urine) were 19.4%, 26.6%, 38.1% and 59.0%, respectively. Rapid urine tests used together diagnosed 69.1% (96 of 139) of cases. This further increased to 80.6% (112 of 139) of cases when combined with sputum Xpert testing. However, of those with CD4 counts <100 cells/μL, 85.1% (63 of 74) could be diagnosed with urine rapid tests alone.
Poster Abstracts

812 Symptom-Based Screening for Tuberculosis Among Pregnant Women Living With HIV in Kenya

Surbhi Modi1, Joseph S. Cavanaugh2, Ray W. Shiraishi3, Barbara Burmen4, Heather Alexander1, Kimberly McCarthy1, Hellen Muttai1, Kevin P. Cain1
1Division of Global HIV/AIDS, Centers for Disease Control and Prevention, Atlanta, GA, United States; 2Division of Tuberculosis Elimination, Centers for Disease Control and Prevention, Atlanta, GA, United States; 3Kenya Medical Research Institute/Centers for Disease Control and Prevention Public Health Collaboration, Kisumu, Kenya; 4Division of Global HIV/AIDS, Centers for Disease Control and Prevention, Atlanta, GA, United States

Background: The World Health Organization (WHO) recommends tuberculosis (TB) screening among people living with HIV (PLHIV) using an evidence-based clinical screening algorithm, but limited data exist on its performance among pregnant women. We assessed the performance of the WHO algorithm among women receiving prevention of mother-to-child HIV transmission (PMTCT) services in Nyanza Province, Kenya.

Methodology: We recruited PLHIV who were newly enrolling in HIV care and treatment at 15 facilities between May 2011 and June 2012, including pregnant women from PMTCT services. All PLHIV were screened with the WHO algorithm and provided two or more sputum samples for smear microscopy, liquid culture, and Xpert MTB/Rif (Xpert). TB was defined as any specimen positive for TB by Xpert or culture. We calculated the performance characteristics of clinical screening compared to laboratory diagnostic testing results, stratified by sex and pregnancy status.

Results: Overall, 131 pregnant women were enrolled, representing 28.0% of the 469 women enrolled in the study and 18.2% of all PLHIV included in the analysis. The median age of pregnant women was 25 years (interquartile range: 22-29 years) and 8 (6.1%) had TB. Preliminary analysis shows that sensitivity, specificity, and negative predictive value of the WHO algorithm in pregnant women were 28.6%, 74.8%, and 94.7%, respectively (Table 1).

Conclusions: The prevalence of TB was low among HIV-infected pregnant women compared to other PLHIV. The WHO algorithm missed more than 70% of pregnant women with laboratory-confirmed TB. Symptom-based screening may have limited utility for TB case finding in PMTCT settings.

813 Highly Multiplexed Detection of Antibodies in Whole Blood During Tuberculosis Infection

Charles Greef1, Greg Husar1, Christen Gray1, David Danks1, Pamela Nabeta1, Mark Perkins1, Michael Lochhead1
1MBio Diagnostics, Inc, Boulder, CO, United States; 2FIND, Geneva, Switzerland; 3Carnegie Mellon University, Pittsburgh, PA, United States

Background: A simple blood test for active TB disease remains a critical unmet need worldwide. Most serodiagnostic assays to date have been based on a single or small number of antigens and have not provided adequate diagnostic accuracy. A hypothesis is that a multiplexed panel of antigen-antibody interactions could provide a signature indicative of active disease. FIND has led a comprehensive TB proteome effort and identified a set of 57 potentially discriminatory antigens. To further down-select to a diagnostic antigen set, it was determined that testing fresh specimens in endemic countries was critical. The portable MBio multiplexed array platform was selected as uniquely suited for this task and a multi-phase clinical research program was initiated. This abstract presents results from the first phase, designed to establish the operational functionality of the MBio system.

Methodology: Disposable assay cartridges incorporating 57 TB proteins and 31 assay controls in a microarray were developed. Cartridges processed with 10 microliters of diluted whole blood or 5 microliters of diluted serum are analyzed on the MBio reader for fluorescence detection of individual antigen-antibody reactivities. A representative image is provided below. To establish performance of the MBio platform, 200 TB suspects were enrolled and tested on systems installed at trial sites in Peru and Vietnam. Endpoints included concordance between the MBio field platforms and a Luminex laboratory reference, indeterminate rate, reliability, and ease of use.
Results: All operational endpoints were met. To compare MBio and Luminex, directional concordance around the mean fluorescence intensity for each antigen was assessed for the collection of frozen serum samples. All antigens showed directional concordance of >75% for all samples, with the majority showing > 90% concordance. The indeterminate rate was 7.4% initially, and after an adjustment of the analysis algorithm, the indeterminate rate decreased to 0.77%. There were zero instrument or software failures over the 673 cartridges tested and user errors were observed in only 2 of 673 cartridges tested.

Conclusions: The MBio system was shown to be a reliable platform for rapidly detecting a large panel of antigen-antibody interactions from whole blood or serum in TB-endemic settings. As a result of this phase I success, the study was advanced to a larger clinical evaluation to investigate diagnostic utility of the array.

814 Performance of the World Health Organization Algorithm for Tuberculosis Screening in Kenya
Surbhi Modi1, Joseph S. Cavanaugh2, Ray W. Shiraishi1, Barbara Burmen3, Heather Alexander1, Kimberly McCarthy2, Hellen Muttai4, Kevin Cain5
1Division of Global HIV/AIDS, Centers for Disease Control and Prevention, Atlanta, GA, United States; 2Division of Tuberculosis Elimination, Centers for Disease Control and Prevention, Atlanta, GA, United States; 3Kenya Medical Research Institute/Center for Disease Control and Prevention Public Health Collaboration, Kisumu, Kenya; 4Division of Global HIV/AIDS, Centers for Disease Control and Prevention, Nairobi, Kenya; 5Division of Tuberculosis Elimination, Centers for Disease Control and Prevention, Kisumu, Kenya

Background: The World Health Organization (WHO) recommends tuberculosis (TB) intensified case finding (ICF) among people living with HIV (PLHIV) using an evidence-based clinical screening algorithm including current cough, fever, night sweats, and weight loss. However, limited data exist on the performance of this algorithm in routine program settings. We assessed the performance of the WHO algorithm alone and with chest radiography among PLHIV in Nyanza Province, Kenya.

Methodology: We recruited PLHIV aged 7 years and older newly enrolling in HIV care at 15 randomly-selected HIV clinics. Patients were screened with the WHO algorithm, underwent chest radiography, and provided two or more sputum samples for smear microscopy, liquid culture, and Xpert MTB/Rif (Xpert). TB was defined as any specimen positive for TB by Xpert or culture. We calculated the performance characteristics of clinical screening compared to laboratory diagnostic testing results.

Results: Overall, 779 PLHIV were enrolled in the study and 718 (92.3%) met criteria for inclusion in the analysis. Median age was 29 years (interquartile range: 24-39 years); 4% were younger than 15 years. Eighty-one patients (11.3%) had TB. Preliminary analysis shows that the sensitivity, specificity, and negative predictive value (NPV) of the WHO algorithm were 73.7%, 50.3%, and 93.8%, respectively (Table 1). Testing asymptomatic persons with chest radiography increased sensitivity and NPV of the screening algorithm to 90.6% and 96.1%, respectively, but decreased specificity to 32.5%.

Conclusions: By limiting TB diagnostic testing to symptomatic patients, the WHO algorithm missed more than 25% of TB patients. Adding a chest radiograph improved case finding and more reliably identified PLHIV who did not have TB and who should receive isoniazid preventive therapy. Additional analyses including screening performance during follow-up visits are needed.

816 Rifapentine Safety and PK With Novel Dosing Strategies To Increase Drug Exposures for TB: ACTG A5311
Kelly E. Dooley1, Rada Savic2, Jeong-Gun Park1, Yoninah Cramer3, Richard Hafner4, Jennifer Janik5, Mark A. Marzinke1, Marc Weiner6, Susan Dorman1, David W. Haas7, and the A5311 Study Team
1Johns Hopkins University School of Medicine, Baltimore, MD, United States, 2University of California, San Francisco, CA, United States, 3Statistical and Data Analysis Center, Harvard School of Public Health, Boston, MA, United States, 4Division of AIDS, National Institute of Allergy and Infectious Diseases, Bethesda, MD, United States, 5Frontier Science Foundation, Amherst, NY, United States, 6Veterans’ Administration Medical Center, San Antonio, TX, United States, 7Vanderbilt University School of Medicine, Nashville, TN, United States

Background: Rifapentine (RPT) is a potent anti-tuberculosis (TB) drug poised to enter Phase 3 trials. Its sterilizing activity and treatment-shortening potential are exposure-dependent. To optimize exposures, RPT must be taken with food, and bioavailability declines with increased dose.

Methodology: This phase 1, two-arm, open-label, multicenter trial in healthy HIV/TB-uninfected subjects investigated two strategies to increase RPT exposures: dividing the dose or giving the drug with an egg (available in many TB-endemic settings). In Arm 1, RPT was administered at 10 mg/kg twice daily (BID) and 20 mg/kg once daily (QD), each for 14 days, separated by a 28-day washout, with randomization of dosing sequence. In Arm 2, 15 mg/kg RPT was given QD with an egg and with a low-fat breakfast, separated by a 28-day washout, with two possible dosing sequences. Intensive pharmacokinetic (PK) sampling was performed after the day-1 and day-14 doses in each dosing period. RPT concentrations were determined by LC-MS/MS. Population PK and PK-toxicity analyses were performed using nonlinear mixed effects modeling in NONMEM. Safety and PK data from Tuberculosis Trials Consortium (TBTC) Study 29X (phase 2 RPT treatment trial) were included in models.

Results: This trial was stopped early because of safety and tolerability concerns. Of 44 subjects, 20 discontinued prematurely, 12 for protocol-defined toxicity (grade 3 or higher adverse event or grade ≥2 rifampicin hypersensitivity (RSH)), including 6 RSH events. Median age and weight were 35 years and 83 kg; 34% were African-American and 27% women. Taking RPT 15 mg/kg with an egg increased population mean steady state AUC (AUC0-24ss) by 47% (95% CI 36, 61) appearance. The sensitivity was unchanged when traces of blood 52% (CI 44, 60) or pre-centrifugation 57% (CI 28, 82) were documented among the clear specimens. An additional 124 specimens generated valid results by XpertMTB/RIF but were contaminated by MGIT (10.5%). There was an early diagnosis of rifampicin (RIF) resistance (9.6%) by XpertMTB/RIF in 25/260 cases.

Conclusions: XpertMTB/RIF’s performance on EPTB specimens provides very promising results and should be considered for incorporation into National TB guidelines. XpertMTB/RIF is less affected by contaminating bacteria and could significantly reduce laboratory labour and the diagnostic delay of culture for EPTB specimens.
Three Months of Weekly Rifapentine + INH for M. tuberculosis Infection in HIV-Infected Persons

Timothy Sterling1, Connie Benson2, Nigel Scott3, Jose Miro4, Guillerme Calvet5, Richard Chaisson6, Alberto La Rosa7, Rosa Infante7, Michael Chen3, Elsa Villarrino5, TBTC / ACTG

Background: Three months of once-weekly rifapentine 900 mg + INH 900 mg under direct observation (3HP) is at least as effective as 9 months of daily self-administered INH (9H) in HIV-uninfected persons, but there are limited data on the effectiveness of 3HP in HIV-infected populations.

Methodology: We enrolled HIV-infected persons ≥2 years old who were tuberculin skin test positive or close contacts of TB cases, into a prospective, randomized, open-label non-inferiority trial of 3HP (directly observed) vs. 9H (self-administered). HIV-infected participants were enrolled from the U.S., Brazil, Spain, Peru, and Canada between June 2001 and December 2010. Participants were followed 33 months from enrollment, and could not receive antiretroviral therapy (ART) until >90 days after enrollment. The endpoint was culture-confirmed TB in adults and culture-confirmed or clinical TB in children. The non-inferiority margin was 0.75%.

Results: There were 399 eligible HIV-infected persons enrolled (MITT population): 193 in the 9H arm and 206 in the 3HP arm. There was no significant difference in the proportion of children <18 years (0.5% vs. 1.5%), history of injection drug use (17% vs. 13%), history of hepatitis C virus infection (14% vs. 11%), median baseline CD4 (524 vs. 496), or receipt of ART >90 days after enrollment (13% vs. 19%) in the 9H vs. 3HP arms, respectively (P > 0.10 for all). There were 6 TB cases in 471 patient-years (p-y) of follow-up from enrollment in the 9H arm (1.27 per 100 p-y) vs. 2 TB cases in 511 p-y of follow-up in the 3HP arm (0.39 per 100 p-y). Cumulative TB rates were 3.69% vs. 1.01% in the 9H vs. 3HP arms, respectively (difference in cumulative TB rate: -2.68%; upper bound of the 95% CI of the difference: 0.55%). In the per-protocol population, cumulative TB rates were 1.90% vs. 0.56% in the 9H vs. 3HP arms, respectively. Of the 8 TB cases, 6 were pan-susceptible, one was resistant to rifampin + pyrazinamide (M. bovis; 3HP arm) and one was resistant to INH + rifampin (9H arm). Among those with CD4+ lymphocyte counts at study entry, the median CD4 was 344 (IQR 271-460) among those who developed TB vs. 512 (IQR 398-704) in those who did not (P = 0.06). Treatment completion was higher in the 3HP (88%) than the 9H (64%) arm (P < 0.001); drug discontinuation due to an adverse drug reaction was similar (3.4% vs. 4.2%; P = 0.80) in 3HP vs. 9H.

Conclusions: In this study conducted in countries with diverse TB prevalence, among HIV-infected persons who did not receive ART for at least the first 3 months, 3HP was non-inferior to 9H. 3HP had higher treatment completion rates and was well-tolerated. 3HP should be considered for treatment of latent M. tuberculosis infection in HIV-infected persons.

Effect of HIV On Latent TB Screening of Pregnant Women in Pune, India

Jyoti S. Mathad1, Ramesh Bhosale1, Savita Kanade1, Prasad Deshpande1, Vandana Kulkarni1, Neetaal Nevekar1, Vidya Mave1, Nishi Suryavanshi1, Nikhil Gupta1, Armita Gupta1

Background: WHO recently recommended isoniazid preventive therapy (IPT) for all HIV-infected pregnant women. Some providers limit IPT to patients with evidence of latent TB infection (LTBI), but the immune changes of both HIV and pregnancy may impact the performance of the most common LTBI tests: the tuberculin skin test (TST) and the IFNγ release assay (IGRA). We compare their performance in HIV-infected and uninfected pregnant women.

Methodology: LTBI screening was done in 128 HIV-infected and 158 -uninfected pregnant women seeking antenatal care at a public hospital in India. Trained staff collected sociodemographics/ medical history and performed IGRA and TST. Agreement using the kappa statistic and percent positivity with binomial exact confidence intervals was calculated. Odds ratios for risk factors of test positivity and discordance were estimated using a logistic regression model adjusting for education, home location, adults in household, TB contact, gestational age (GA), and HIV.

Results: Compared to HIV-uninfected women, HIV-infected women had similar GA (25 vs 26 weeks, p=0.38) and prior IPT (0% vs 0%) but more known TB contacts (7% vs 2%, p=0.03). Median CD4 count for HIV-infected women was 530 cells/mm3 (IQR 393-708); 43 (36%) were on antiretroviral treatment (ART).

All women had higher IGRA positivity than TST whether HIV-infected (29% vs 11%, p=0.01) or not (32% vs 17%, p=0.01). Women with HIV had lower, but not significantly lower, IGRA (29% vs32% p=0.63) and TST positivity (11% vs 17%, p=0.20) than HIV-uninfected women. In multivariate analysis, positive IGRA was associated with having a TB contact (aOR 2.9, CI 0.9-8.9, p=0.05).

Agreement of TST and IGRA was moderate in HIV-infected women (κ=0.40, CI: 0.24-0.56) but poor in HIV-infected women (κ=0.21, CI 0.02-0.41). There was a trend to lower concordant TST+/IGRA+ in HIV-infected than HIV-uninfected (7% vs 15%, p=0.08) but similar rates of TST-/IGRA- (57% vs 62%, p=0.82) TST-/IGRA+ (18% vs 17%, p=0.92), and TST+/IGRA- (4.6% vs 4.2%, p=0.7). In multivariate analysis, TST-/IGRA+ discordance was associated with having a TB contact (aOR 3.2, CI 1.0-10, p=0.04). HIV-infected women with TST-/IGRA+ had significantly lower IFNγ concentration than TST+/IGRA+ (1.8 vs 6.4 IU/mL, p=0.02). This was not significant in HIV-uninfected (2.2 vs 4 IU/mL, p=0.12).

Conclusions: Discordance between the IGRA and TST is common in pregnant women, the IGRA returned significantly more positives in both HIV-infected and -uninfected women. HIV-infected women with TST-/IGRA+ discordance had lower IFNγ levels than non-discordant women, suggesting that insufficient IFNγ negatively affects TST performance. The reliance on TST for LTBI screening in antenatal programs may cause >50% of HIV-infected women to miss out on lifesaving IPT.
Baseline Inflammatory and Immune Activation Markers Predictive of TB After ART Initiation

Mark Tenforde1, Nikhil Gupte1, David Dowdy2, David Asmuth3, Ashwin Balagopal4, Richard Pollard4, James Hakim4, Richard Semba5, Thomas Campbell6, Amita Gupta1, for the ACTG A5175 (PEARLS) and NWCS 319 Study Group

1Medicine, Johns Hopkins University, Baltimore, MD, United States, 2Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, 3University of California Davis, Medical Center, Sacramento, CA, United States, 4University of Zimbabwe College of Health Sciences, Harare, Zimbabwe, 5Johns Hopkins University, Baltimore, MD, United States, 6University of Colorado Denver, Aurora, CO, United States

Background: Incident tuberculosis disease (TB) remains a major cause of mortality after antiretroviral treatment (ART) initiation in resource-limited settings. Pre-ART inflammation and immune activation may impact host risk for TB. Our objective was to determine the association between baseline inflammation and immune activation and risk of pulmonary and extra-pulmonary TB after ART initiation in adults in resource-limited settings.

Methodology: We conducted a nested case-control study (n=332) within the ACTG PEARLS trial of three ART regimens among 1575 HIV-infected treatment naïve adults in 9 countries. Cases were incident TB cases by 96 weeks after ART initiation, and controls were a random sample (stratified by study site) of those who did not develop TB during follow-up. Primary outcomes were associations between pre-ART immunologic and inflammatory marker levels (CRP, ferritin, IFN-gamma, IL-6, IP-10, TNF-alpha, EndoCab IgM, LPS, sCD14) and incident TB. Using univariate and multivariable logistic regression, we calculated odds ratios of association between markers and incident TB. We defined markers according to established cutoff definitions when available and the 75th percentile of measured values when not. Multivariable analyses adjusted for age, sex, study site, treatment arm, baseline CD4, and log₁₀ viral load.

Results: The cumulative incidence of TB at 96 weeks after ART initiation was 4.9% (55 pulmonary and 22 extra-pulmonary TB cases), of which 53% (41 cases) occurred within the first 6 months of treatment. CRP and IP-10 were associated with incident TB in both unadjusted and adjusted analysis (aOR for CRP, 4.12, 95%CI: 2.18-7.77; aOR for IP-10, 1.89, 95% CI: 1.05-3.39). More established TB risk factors, including hypoalbuminemia (aOR 5.24, 95%CI: 2.69-10.20) and hemoglobin <12 g/dL in women or <13 g/dL in men (aOR 2.16, 95%CI: 1.07-4.35) were also significantly associated with incident TB; being overweight or obese versus of normal BMI was inversely associated with incident TB (aOR 0.37, 95%CI: 0.14-0.97).

Conclusions: Incident TB occurs commonly after ART initiation in resource-limited settings. IP-10 and CRP, coupled with traditional risk factors, may have value in identifying patients most at risk for developing TB after initiation of ART. Use of CRP in particular may have added value to identifying those at greatest risk of incident TB post-ART initiation.

MAIT Cells Are Highly Enriched in the Bronchoalveolar Lavage Fluid of Patients With TB

KwaZulu Natal Research Institute for Tuberculosis and HIV, Durban, South Africa, Division of Infectious Diseases, Massachusetts General Hospital, Boston, MA, United States, Division of Pulmonary and Critical Care Medicine, Oregon Health & Science University, Portland, OR, United States, Division of Infectious Diseases, Massachusetts General Hospital, Boston, MA, United States, Department Veterans Administration Medical Center, Portland, OR, United States, Department Pulmonology and Critical Care, Nelson R. Mandela School of Medicine, Durban, South Africa, Department of Pulmonology and Critical Care, Nelson R. Mandela School of Medicine, Durban, South Africa, HIV Pathogenesis Programme, University of KwaZulu Natal, South Africa, Division of Infectious Diseases, Johns Hopkins School of Medicine, Baltimore, MD, United States

Background: Mucosal Associated Invariant T (MAIT) cells are a class of non-conventional CD8+ lymphocytes that respond to a broad range of bacterial, mycobacterial and fungal pathogens. They have been defined by their usage of a semi-invariant T cell receptor (TRAV1-2 TRAJ33) and can be activated by microbial riboflavin metabolites presented by the evolutionarily conserved MR-1 molecule. Though found in people who have no history of TB exposure, M.tb-reactive MAIT cells are absent in the peripheral blood of those with active TB. This observation led us to hypothesize that during pulmonary TB MAIT cells leave the peripheral circulation to participate in the lung’s mucosal immune response.

Methodology: Bronchoalveolar lavage (BAL) fluid was collected from a cohort of patients undergoing clinically indicated bronchoscopy in Durban, South Africa. Pulmonary TB cases were defined microbiologically (positive M.tb. culture or PCR); controls were defined as having no evidence of inflammatory or infectious lung disease (negative bacterial, fungal and mycobacterial BAL cultures and no eventual diagnosis of sarcoidosis or interstitial lung disease). BAL cells were characterized by flow cytometry to assess the frequency of MAITs (TRAV1-2+) among CD8+ T cells (gated on live, CD14-negative, CD3+ lymphocytes). When sufficient cells were obtained, they were stimulated with CD2/CD3/CD28 beads to assess the production of TNFα and IL-17 by intracellular cytokine staining. When available, matched PBMC were also analyzed for the frequency of peripheral MAIT cells. The Mann-Whitney U test was used to compare frequencies.

Results: In pulmonary TB cases, MAIT cells comprised a significantly higher percentage of lung-resident CD8+ T cells (n=8, median 22.9%, IQR 16.4-33.9%) than in controls (n=11, median 5.0%, IQR 4.3-5.8%, p=0.0005). In contrast, during pulmonary TB, TRAV1-2+ CD8+ T-cells were not expanded in the peripheral blood (n=5, median 5.8%, IQR 5.6-6.2%, p=0.0016). Upon non-specific activation, lung resident MAIT cells in those with pulmonary TB produced very high levels of TNFα and did not produce IL-17 above background.

Conclusions: MAIT cells, an emerging class of innate lymphocytes, are highly enriched in the lungs during pulmonary TB. Interestingly, though it has been shown that HIV severely depletes MAITs in the peripheral blood, here we find MAITs to be comparably enriched in the lungs of both HIV-positive and HIV-negative patients during active tuberculosis. This suggests that MAITs are redistributed to mucosal surfaces rather than destroyed by HIV. Further research on the role of MAIT cells in protective immunity against TB is urgently needed; their potential as a novel TB vaccine target should be explored.

Vitamin D and TMEM16J Host Variants Associated With TB or Death in HIV-Infected and -Exposed Infants

Amita Gupta, Jennifer Jubulisi, Bret Zeldow, Grace Montepiedra, Barbara Detrick, Avy Violari, Shabir A. Madhi, Charles Mitchell, Stephen A. Spector, for the IMPACT NWCS113 and P1041 Study Team

Division of Pulmonary and Critical Care Medicine, Stanford University, Stanford, CA, United States, Department of Pathology, Johns Hopkins University, Baltimore, MD, United States, United States, Department of Public Health, Johns Hopkins University, Baltimore, MD, United States, United States, University of the Witwatersrand, Johannesburg, South Africa, University of the Witwatersrand, MRC: Respiratory and Meningeal Pathogens Research Unit, Johannesburg, South Africa, University of Miami Miller School of Medicine, Miami, FL, United States, Medical University of California San Diego, La Jolla, CA, United States

Background: While young African children have been severely affected by HIV and TB, host genetic single nucleotide polymorphisms (SNPs) that alter the Vitamin D receptor, affect Vitamin D insufficiency and deficiency (VDID) and pose a potential risk for tuberculosis (TB), have not been well studied.

Methodology: We performed a case-cohort study (total n=346 with a random subcohort of 270) in IMPACT P1041, a trial in South Africa that evaluated the efficacy of isoniazid prophylaxis on reducing TB disease in 1351 HIV-infected and -exposed infants. Vitamin D levels were determined by chemiluminescent immunoassay. Five Vitamin D related SNPs (Bsm-1-G/A [rs1544410], Fok-I-C/T [rs2228570], GC-A/C [rs2282679], DHRC7/ NADSYH1-G/T [rs12758578] and CYP2R1-G/A [rs10741657]), and three SNPs in the PKP3-SIGIRR-TMEM16J region associated with TB susceptibility [PKP3 (rs10902158-A/G), PKP3 (rs7105848-T/C), and TMEM16J [rs7111432-G/A]] were assessed by real-time PCR. Primary outcome was time to probable/definite TB by 192 weeks. Secondary outcomes included time to possible, probable, or definite TB; time to latent TB/TB disease; and time to TB or death. Prevalence of VDID, defined as 32 ng/ml, was determined using the random subcohort. To determine the associations between VDID and host SNPs with outcomes, Cox regression was performed.

Results: Median age at Vitamin D draw was 8 months; 11% were ever breastfed; 51% were HIV-infected. VDID prevalence was 26%. There were 138 TB cases (43 definite/probable, and 95 possible) and 26 deaths included in this analysis. Children with VDID had a 77% greater risk of probable/definite TB (HR 1.77, p = 0.17). When possible TB was included in the outcome, VDID was associated with a significant increase in TB (HR 1.99, p = 0.005). VDID was also associated with any TB or death (HR 2.05, p = 0.002). Adjusting for HIV status, season, site, sex, weight-for-age z score, breastfed, type of house, mother previous TB diagnosis, age at plasma draw date, and INH/placebo treatment arm, VDID was independently associated with any TB (aHR 1.75, 95% CI 1.01-3.05; p = 0.046) as well as any TB or death (aHR 1.76, 95% CI 1.03-3.00; p = 0.038). No polymorphism was associated with VDID. In both crude and adjusted models, however, having the TMEM16J G-allele was protective of probable/definite TB (aHR 0.53, p = 0.07), any TB (aHR 0.56, p = 0.017), any TB/death (aHR 0.59, p = 0.016) and any TB/latent TB (aHR 0.58, p = 0.009); having GG polymorphism of the PKP3 genetic variant was marginally associated with increased risk of any TB/death (aHR 1.44, p = 0.07).

Conclusions: In young children with or without HIV, VDID was associated with nearly a 2-fold increased risk of TB or death. Additionally, specific SNPs that affect innate immunity altered the risk for TB.
Background: Virulence factors (VF) facilitate persistence of Mycobacterium tuberculosis (MTB) and are implicated in the recent emergence of new human MTB isolates. However, some VFs are lineage specific and thus difficult to study. Understanding of VFs is essential for the development of new drugs and vaccines against MTB. We therefore sought to identify new VF/markers of virulence in Central Asian (CAS) clinical isolates.

Methodology: Three large–cluster CAS isolates, designated 6, 14 and 72, from the East-African Indian (EAI) lineage were studied in guinea pigs and human monocyte-derived macrophages (MDMs). References were isolates E and 1, from East-Asian and Euro-American lineages respectively, and also in MDMs unique CAS isolate 40, reference strains H37Rv/Ra, and BCG. Pathogenicity scores (PS) were used to assess the severity of lesions in the lungs of infected animals. PS are derived from blind yet subjective scoring of consolidation, necrosis and calcification. Colony forming units (CFU) recovered from spleen samples of infected animals were used to measure dissemination of isolate within host. MTB intracellular replication ex vivo was measured by flow cytometry (median fluorescence intensity) on CD4+ and CD8+ T lymphocytes in the no TB and LTBI groups. Plasma concentrations of the soluble markers were measured by ELISA or multiplexed bead-based immunosassays in all three groups. The Mann Whitney Wilcoxon test was used for comparisons.

Results: All groups were well matched for CD4 and HIV viral load. Subjects with LTBI expressed higher levels of CD38 and CD8+ T-cells and CD38 on CD4+ T-cells compared to those with no TB (p=0.0014, p=0.0443, and p=0.0378). Those with active TB had elevated plasma levels of CRP, IL-6 and IP-10 (p=0.0001, p=0.0005, and p=0.0150) compared to those with no TB. LTBI was not associated with elevated plasma concentrations of any of the soluble biomarkers.

Conclusions: Both active and latent TB infection elevated markers of immune activation and inflammation that have previously been shown to predict more rapid disease progression in HIV-infected individuals. While elevation of inflammatory markers in active TB is not surprising, it is an important new observation that LTBI can independently increase harmful T-cell activation. These results suggest that in the highly TB- and HIV-endemic settings of Southern Africa, latent TB infection may contribute to HIV disease progression and exacerbate the HIV epidemic. Further work to determine if treatment of LTBI improves lymphocyte activation is needed, as this would provide an additional rationale for the widespread use of isoniazid preventative therapy (IPT) in those with HIV and LTBI.

823 Ex Vivo Fitness of MTB Correlates With Lysozyme Sensitivity in the East-African Indian Lineage
Claire Pardieu1, Nicola Casali1, Simon Clark2, Ann Rawkins1, Richard Hooper1, Preya Veli1, Ximena Gonzalez1, Jane R. Deayton2, Francis A. Drobniewski4
1Clinical TB and HIV Group, Queen Mary University of London, London, United Kingdom, 2TB Research Group, Public Health England, Salisbury, United Kingdom, 3Centre for Primary Care and Public Health, Barts and The London School of Medicine and Dentistry, London, United Kingdom, 4National Mycobacterium Reference Laboratory, Public Health England, London, United Kingdom

Background: Ex vivo fitness of MTB correlates with lysozyme sensitivity in the East-African Indian (EAI) lineage. We therefore sought to identify new VF/markers of virulence in EAI clinical isolates.

Methodology: Three large–cluster CAS isolates, designated 6, 14 and 72, from the East-African Indian (EAI) lineage were studied in guinea pigs and human monocyte-derived macrophages (MDMs). References were isolates E and 1, from East-Asian and Euro-American lineages respectively, and also in MDMs unique CAS isolate 40, reference strains H37Rv/Ra, and BCG. Pathogenicity scores (PS) were used to assess the severity of lesions in the lungs of infected animals. PS are derived from blind yet subjective scoring of consolidation, necrosis and calcification. Colony forming units (CFU) recovered from spleen samples of infected animals were used to measure dissemination of isolate within host. MTB intracellular replication ex vivo was measured by qPCR for bacterial gene SigA relative to human gene TERT. Whole-genome sequencing was performed for each CAS, Illumina sequence reads mapped onto the H37Rv genome and single nucleotide polymorphisms (SNPs) identified using ssaha_pileup. To determine in vitro lysozyme (LYZ) sensitivity, CAS isolates and reference strains were plated on 7H10 plates at increasing concentrations of LYZ and CFUs recovered at 3 weeks.

Results: Differences in PS and CFU were observed in vivo but only differences in fitness ex vivo were statistically significant; 72 was the slowest isolate (Figure 1). Comparative genomic analysis revealed 123 unique non-synonymous SNPs as candidates for the observed differential phenotype of 72. Of these, 10 locate in genes previously associated with fitness ex vivo or dissemination in vivo; 3 genes were additionally linked to both acid and LYZ resistance in vitro. Accordingly, sensitivity studies showed that growth of all isolates was inhibited by increasing concentration of LYZ with the strongest correlation seen for isolate 72.

Conclusions: Early work linked LYZ sensitivity to MTB fitness and dissemination in vivo, but for Euro-American reference strain H37Rv only. We now describe a similar correlation for EAI clinical isolates. Further work will determine whether genes conferring LYZ resistance are VFs per se.
824 Polyfunctionality of TB-Specific CD4+ T-Cells in HIV-TB Co-Infection in Latent and Pulmonary TB

Puja Van Epps1, Sankar Sridaran2, Htin Aung3, Michael R. Betts4, Zahra Toosi4, David H. Canaday2, 4

1Department of Medicine, Division of Infectious Diseases and HIV Medicine, Case Western Reserve University, Cleveland, OH, United States, 2Geriatric Research Education & Clinical Center (GRECC), Louis Stokes Cleveland VA Medical Center, Cleveland, OH, United States, 4Department of Microbiology, University of Pennsylvania, Philadelphia, PA, United States

Background: HIV+ persons with latent tuberculosis infection (LTBI) have a 10% annual risk of developing active tuberculosis (TB) compared to a 10% lifetime risk in HIV-uninfected individuals. Mean CD4 + T cell counts of HIV+ patients with pulmonary TB (PTB) are higher than seen with other opportunistic infections suggesting that progression to active TB in this setting is not merely due to CD4 + T cell depletion, but may also be related to functional impairment of CD4 + T cells. There is limited data examining T cell functional signatures in human HIV-TB co-infection. Here we compare CD4 + T cell cytokine profiles and polyfunctionality in response to M. tuberculosis (MTB) antigens between TB uninfected, LTBI and PTB in HIV+ adults.

Methodology: HIV+ adults recruited in Kampala, Uganda were differentiated into 3 groups: PTB (positive sputum smear and/or culture for MTB; n=7), LTBI (>5mm response to the tuberculin skin test (TST) and negative chest x-ray; n=15), or TST- (negative TST and chest x-ray; n=15). Multicolor flow analysis was performed on PBMC stimulated with either PPD, ESAT+CFP10, or SEB, and frequencies of IL-2, IFN-γ and TNF-α secreting cells were determined within the memory subset of CD4+ T cells. Polyfunctionality was determined using FlowJo and SPICE software.

Results: PPD-specific CD4+ T cell secretion of TNF-α and IFN-γ was higher in LTBI compared with TST- group (p=0.001 and p=0.002 respectively). Although LTBI group generally had higher cytokine responses when compared to PTB group, this did not reach statistical significance. Cytokine responses to both PPD and ESAT+CFP10 stimulation correlated positively with TST measured in millimeters (mm). All polyfunctional CD4+ T cell response groups that contained TNF-α correlated with an r>0.43 p<0.01. The polyfunctional CD4+ T cell response profile of MTB-specific CD4+ T cell responses were similar in LTBI and PTB groups with the TNF-α-only secreting cells being the most abundant phenotype. In both groups, PPD-specific cells were less polyfunctional with a greater TNF-α bias than memory cells activated with mitogen.

Conclusions: CD4+ T cell cytokine responses to MTB-specific antigens were significantly higher in LTBI compared to TST- HIV+ adults. ESAT-specific CD4+ T cell responses correlated positively with TST in mm suggesting that TST response in Ugandans, reflective of TB-specific antigen infection with MTB rather than BCG vaccination. Published data suggests polyfunctional CD4+ T cell profiles differ between LTBI and PTB among HIV-uninfected individuals. The fact that we did not observe such a difference in MTB antigen responses in HIV+ subjects suggests that LTBI may represent a more “smoldering” TB state. This may help explain the significantly increased risk of progression to active TB in this population.

Impact of ART On TB Risk and Disease

825 Increased Risk of TB and Persistent Immune Deficit With Delayed ART: A Randomized Trial From Haiti

Sean E. Collins1, Marc Antoine Jean Juste2, Patrice Sereve2, Serena P. Koenig3, Rode Secours4, Oksana Ocheretina4, Daphne Bernard4, Allison Dunning3, Sandra M. Hurtado Rúa4, Jean W. Pape1, 2

1Center for Global Health, Department of Medicine, Weill Cornell Medical College, New York, NY, United States, 2Groupe Haitien d’Etude du Sarcome de Kaposi et des Infections Opportunistes, Port au Prince, Haiti, 3Division of Global Health Equity, Brigham and Women’s Hospital, Boston, MA, United States, 4Department of Public Health, Weill Cornell Medical College, New York, NY, United States

Background: The long-term (5 year) effect of early initiation of antiretroviral therapy (ART) versus delayed initiation of ART on immune recovery and risk for tuberculosis (TB) infection in HIV-1 infected individuals is not certain.

Methodology: We conducted an open label randomized controlled trial of immediate initiation of ART in HIV-infected adults with CD4 counts between 200 and 350 cells/mm3 versus deferring ART until the CD4 count was below 200. The primary comparisons were CD4 counts over time and the risk for incident TB during 5 years of follow-up. Generalized estimating equations were used to compare CD4 counts between groups, probability of TB-free survival was calculated using Kaplan-Meier survival methods. Univariate and multivariate Cox proportional hazards regression models were used to estimate the risk of TB as hazard ratios (HR) with 95% confidence intervals. The trial is registered at ClinicalTrials.gov with study number NCT00120510.

Results: 816 participants were enrolled, 408 in each treatment arm. The median age was 40 and 58% of participants were women. The early group started ART within 2 weeks, the deferred group started ART a median of 1.3 years after enrollment. After 5 years, the mean CD4 count in the early group was significantly higher than in the deferred group; 574

---

**Figure 1:** Kaplan-Meier estimates of the probability of tuberculosis free survival from the time of study randomization.
cells/mm³ (95% confidence interval [CI] 545 to 603) versus 451 cells/mm³ (95% CI 419 to 484; p<0.0001). Risk for incident TB was significantly higher in the deferred group five years after randomization (hazard ratio [HR] 2.44 [95% CI 1.56-3.70]; p<0.0001). In a time dependent multivariate analysis, TB risk correlated with lower CD4 counts and with lower Body Mass Index. For each CD4 decrease of 50 cells/mm³ the hazards of incident TB increased by 1.30 (95% CI 1.16-1.43; p<0.0001).

**Conclusions:** Short delays in ART initiation for HIV-infected adults with CD4 counts of 200 - 350 cells/mm³ can result in long-term (5 year) immune dysfunction and persistent increased risk of tuberculosis.

---

**826 Viral Suppression in HIV-Infected Pregnant Women With and Without TB, South Africa**

**Jennifer Hoffman**, Silvia Cohn, Fildah Mashabela, Reginah Msandiwa, Richard Chaisson, Neil Martinson, Tshepiso Study Team

**Background:** HIV and tuberculosis (TB) are the leading infectious causes of death among women of reproductive age worldwide. In South Africa, the burden of overlapping HIV and TB epidemics is exceptionally high. Nearly 30% of pregnant women presenting for prenatal care are HIV-infected. HIV/AIDS is the leading cause of maternal death in South Africa, responsible for at least 20% of all maternal deaths. Antiretroviral therapy during and after pregnancy is essential for maternal health and prevention of mother to child transmission. We describe the HAART and viral suppression in a cohort of HIV-infected pregnant women with and without TB.

**Methodology:** Tshepiso is a prospective cohort study of HIV-infected pregnant women with TB (cases) and matched HIV-infected pregnant women without TB (controls) in Soweto, South Africa. Women are enrolled prenatally and followed during delivery, and then mother-infant pairs are followed to one year postpartum for HIV and clinical outcomes.

**Results:** From January 2011 to September 2013, we enrolled 185 HIV-infected pregnant women, 61 TB/HIV cases and 124 HIV controls. At enrollment, median age was 28 and 29 years, and median gestational age was 29 and 30 weeks for cases and controls respectively. At baseline, 59% of cases and 57% of controls were taking HAART and the median [IQR] CD4 count was 283 [142,433] and 371 [271,487] for cases and controls respectively (p=0.0009). Among women on HAART, 38% of cases and 62% of controls had undetectable viral load (p=0.02). At delivery 82% of cases and 64% of controls were on HAART with 52% and 86% having an undetectable viral load respectively (p=0.03). One year postpartum 79% of cases and 69% of controls reported taking HAART, only 56% of cases and 60% controls had undetectable viral loads (p=0.76).

**Conclusions:** Pregnant women with TB/HIV had less viral suppression prenatally and at delivery than those without TB. Uptake of HAART for TB co-infected women was inadequate. Our cohort revealed suboptimal viral suppression at one year postpartum for both cases and controls taking HAART. Option B+ can have a significant impact in improving maternal and infant survival if women are appropriately initiated on HAART and viral suppression is maintained. Our cohort demonstrates the potential programmatic need for additional peripartum adherence interventions and monitoring.

---

**827 Depleted DHEA-S Reserves Are Associated With Early Mortality After ART Initiation in HIV/TB**

**Shruthi Ravimohan**, Neo Tamuhla, Andrew P. Steenhoff, Rona Lethogile, Kebatshabile Ntanyana, Tumelo Rantereu, Michael Adu, Drew Weissman, Gregory P. Bisson

**Background:** Early mortality post-ART initiation in advanced HIV/TB co-infection is associated with poor pathogen-specific immunologic recovery despite virologic suppression. The active form of dehydroepiandrosterone-sulfate (DHEA-S), DHEA, an adrenal androgen, enhances Th1 responses in HIV/TB and is available as an over-the-counter supplement. We hypothesized that low pre-ART (baseline) DHEA-S levels are associated with early mortality in advanced HIV/TB.

**Methodology:** We conducted a nested case-control study within a cohort evaluating factors associated with death within 6 months post-ART initiation in ART-naïve adults with HIV/TB and pre-ART CD4 counts <125 cells/μl, in Botswana. Baseline DHEA-S levels (primary exposure) were compared between cases (deaths, n=17) and controls (survivors, n=35). CD4 counts, cortisol, and IL-6 levels were also assessed at baseline (pre-ART) and week 4 post-ART initiation using the rank sum test. Logistic regression was used to adjust for baseline CD4 count and sex.
Results: DHEA-S was significantly lower in cases vs. controls at baseline (0.21μg/ml [IQR 0.11-0.37] vs. 0.45μg/ml [IQR 0.19-0.77]; p=0.007). Adjusting for CD4 count and sex, every 0.1μg/ml higher baseline level of DHEA-S was associated with a 24% decrease in the odds of early mortality (odds ratio, 0.76 [95% CI, 0.59-0.98]). DHEA-S continued to be lower among deaths vs. survivors at week 4 post-ART initiation (p=0.014). Baseline levels of CD4 counts, cortisol, and IL-6 did not differ between deaths vs. survivors. However at week 4 post-ART initiation, change from baseline and absolute CD4 counts were lower, while cortisol and IL-6 levels were significantly higher, in deaths vs. survivors.

Conclusions: Diminished DHEA-S reserves, increased immune activation, and poor immune recovery are associated with increased risk of early mortality in advanced HIV/TB. DHEA has been shown to alter T-regulatory cell function by downregulating FoxP3 expression and enhancing dendritic cell function in vitro, which is essential for mounting protective antigen-specific immune responses. An inability to effectively fight Mycobacterium tuberculosis in advanced HIV/TB may be in part due to depleted DHEA-S reserves. Exploratory trials of DHEA supplementation to improve immune response and outcomes should be pursued in HIV/TB.

829 Impacts of National ART Initiation Policy Change On Integrated TB HIV Practice in Zomba, Malawi
Kevin D. Bezanson1, Adrienne K. Chan2, Monique van Lettow2, Jean Bourgeois1, Edson Mawire3, Harry Mbeve1, Martin Kachingwe1, Donald Cole3, Sumet Sodhi3
1Dignitas International, Toronto, ON, Canada, 2Dignitas International, Zomba, Malawi, 3Zomba Central Hospital, Zomba, Malawi, 4Dalla Lana School of Public Health, Toronto, ON, Canada

Background: In response to emerging evidence for the safety and clinical benefit of early Antiretroviral (ART) initiation in tuberculosis (TB) patients, the National TB Programme (NTP) in Malawi implemented a change in policy for TB patients co-infected with Human Immunodeficiency Virus (HIV) in September 2011. Clinicians were advised to start ART as soon as possible, rather than delaying initiation until 2 weeks after starting TB treatment. We sought to assess the impact of the policy change on integrated TB HIV program measures and treatment outcomes in a TB HIV clinic at Zomba Central Hospital (ZCH).

Methodology: Routine program data from NTP TB registers and ART Clinic were collected and analyzed for all TB patients enrolled at ZCH April 1, 2011 to April 1, 2012. Univariate comparisons were made between groups enrolled 6 months prior to policy change implementation, and the subsequent 6 months.

Results: All 842 patients were included. 50.2% (n=423) pre, and 49.8% (n=419) post guideline change. No significant differences were found between groups in age, gender, type of TB (pulmonary/extra-pulmonary), or TB episode type (new/relapse/failed/return after default).

Program measures of TB HIV integration revealed significantly more patients already on ART being diagnosed with TB in the post-guideline change group, 36.8% (n=154) vs. 30.0% (n=127), p=0.038. Of those not already on ART, rates of HIV testing exceeded 90% and were not different between groups.

Furthermore, in those initiating ART, significantly more did so in less than 2 weeks, increasing from 31.1% (n=33) to 68.1% (n=64), p<0.001. TB treatment outcomes revealed more patients alive at the end of treatment in the pre-guideline change group 86.3% (n=365) vs. 79.0% (n=331), p=0.005. This was likely due to higher unknown outcomes in the post-guideline change group 9.5% (n=40) vs. 2.8% (n=12), p<0.001, as rates of death were not different between groups.

Conclusions: The national policy change from delayed to early as possible ART initiation in TB patients in Malawi was reflected in clinical practice in our clinic. More patients who tested HIV positive were successfully initiated on ART, and earlier. Increases in patients being diagnosed with TB already on ART were also found, raising the potential that changes in vigilance of TB diagnosis prior to ART initiation occurred as well. These changes did not appear to affect overall mortality. They do suggest an impact of health policy change on service delivery.

830 Does Long-Term ART Reduce TB Rates To Background Population Levels? Data From a National HIV Cohort
Rishi K. Gupta1, Marc Lipman2, Alison Brown1, Brian Rice3, Anton Pozniak1, Dominik Zennner1, Lucy Thomas1, Ibrahim Abukakar1,2, Valerie Depech1
1University College London, London, United Kingdom, 2Public Health England, London, United Kingdom, 3Chelsea and Westminster NHS Foundation Trust Hospital, London, United Kingdom

Background: Antiretroviral therapy (ART) promotes immune reconstitution and is associated with a time-dependent reduction in HIV-associated tuberculosis (TB) incidence. It is not known if TB rates in individuals on long-term ART remain elevated compared to the background population, particularly in low TB prevalence areas.

Methodology: National HIV positive cohort records were linked to the national TB register for England, Wales & Northern Ireland. TB incidence in the HIV positive cohort was calculated for 2007-11. This was compared to HIV negative population rates in 2009 (middle year of HIV positive cohort), calculated using Office for National Statistics denominators (minus those seen for HIV care in 2009). TB cases were assumed to be HIV negative if they did not match the national policy change from delayed to early as possible ART initiation in TB patients in Malawi was reflected in clinical practice in our clinic. More patients who tested HIV positive were successfully initiated on ART, and earlier. Increases in patients being diagnosed with TB already on ART were also found, raising the potential that changes in vigilance of TB diagnosis prior to ART initiation occurred as well. These changes did not appear to affect overall mortality. They do suggest an impact of health policy change on service delivery.

Results: The HIV positive cohort included 79,919 adults with 231,664 PY of follow up; 50% were white, and 36% were black-African. At cohort entry, median CD4 was 409 cells/μL and 49% were on ART. There were 1,550 TB cases (6.7/1000 PY) during HIV positive cohort follow up; 60% of these were within 3 months of HIV diagnosis. TB incidence was higher in black-Africans than in the white population (13.6/1000 vs. 1.7/1000 PY) and declined as time on ART increased [Fig. 1]. Lower most recent CD4 count, non-white ethnicity, not being on ART and early ART (0-3 months) were independent risk factors for TB in the HIV positive cohort in multivariate analysis. TB incidence in the HIV positive population during long-term ART (≥5 years) was similar to that in the HIV negative population in black-Africans (2.5/1000 vs. 1.9/1000 PY; p>0.05) but was higher than the incidence in the HIV negative population in the white ethnic group (0.5/1000 vs. 0.04/1000 PY; p<0.001). This higher TB incidence in the HIV positive white group persisted when the
analysis was restricted to person-time accrued on ART with CD4 ≥ 500 cells/μL and when white HIV positive patients born abroad were excluded.

**Conclusions:** TB incidence during long-term ART (≥5 years) was similar to that in the HIV negative population in black-Africans but rates were high in this ethnic group, regardless of HIV status. In contrast, incidence during long-term ART in the white HIV positive population, while low overall, was higher than in HIV negative individuals. Underlying reasons for this in this low TB burden setting require further investigation.

831 Development of Tuberculosis in HIV-Infected Patients Receiving Successful TARGA

Esteban Martín-Echevarría1, Sergio Serrano Villar2, Talía Sainz2, Ana Moreno2, Jose Luis Casado2, Fernando Dronda2, Maria Jesus Perez Elias2, Enrique Navas2, Manuel Rodriguez Zapata2, Santiago Moreno2

1Hospital Universitario Guadalajara, Guadalajara, Spain, 2Hospital Universitario Ramón y Cajal, Madrid, Spain

**Background:** The incidence of active tuberculosis in HIV-infected patients receiving antiretroviral therapy (ART) is still significantly higher than that observed in the general population. We hypothesized that an optimal immunological recovery may reduce the risk of tuberculosis.

**Methodology:** Historical cohort study in ART-treated patients without previous diagnosis of tuberculosis. Tuberculosis was diagnosed only if microbiologically proven. Multivariate analyses were performed to identify risk factors associated with tuberculosis.

**Results:** This study included 1824 patients, with a median follow-up of 473 days. Higher CD4 count gain after ART initiation was a protective factor against active tuberculosis (per each 100 cells/μL increase, OR, 0.683; 95% CI, 0.522-0.894). The maximal protection was observed in patients reaching increments ≥150 cel/μL after 12 months (OR, 0.29; 95% CI 0.11-0.8) or ≥300 cel/μL after 24 months (OR, 0.73; 95% CI 0.71-0.75) of ART. CD4+ cell increase after ART initiation was confirmed as an independent predictor of development of tuberculosis by Cox regression analysis (per each 100 cell/uL at year one, HR 0.63; 95% CI, 0.43 - 0.94; per each 100 cell/uL at year two; HR, 0.57; 95% CI, 0.41 - 0.81). However, there was no association between achieving HIV RNA <50 copies/mL and the risk of active TB (OR, 1.43; 95% CI, 0.68-2.49).

**Conclusions:** The risk of tuberculosis in patients starting ART is reduced among those with better immunological response and it is unrelated to the virological response. Our results emphasize the need of adjunctive strategies in immunological non-responders in order to minimize the residual risk of tuberculosis.

832 Timeliness of ART Initiation Among HIV-Infected Patients With TB in Sub-Saharan Africa

1ICAP, Columbia University, New York, NY, United States, 2Department of Epidemiology, Columbia University, New York, NY, United States

**Background:** Initiating antiretroviral therapy (ART) early during TB treatment increases survival among people living with HIV (PLWH). 2010 WHO guidelines recommend ART initiation for PLWH as soon as possible after TB treatment initiation, regardless of CD4+ count. Yet, globally, only 48% of PLWH with TB were on ART in 2011.

**Methodology:** We used routinely-collected data for adult PLWH newly enrolled in HIV care from 05/2003-03/2013 at 74 health facilities supported by ICAP-Columbia University in Mozambique (MZ) and Rwanda (RW) to compare time from enrollment into HIV care to ART initiation in relation to country adoption of 2010 WHO guidelines as follows: 1) Prior to adoption , between ART-eligible patients without and with TB; and 2) after adoption, between ART-eligible patients without TB and all patients with TB at enrollment. “On TB treatment at enrollment” variable was used to identify patients with TB at enrollment. We used stratified Kaplan-Meier survival curves for our analyses.

**Results:** Of total of 179,086 PLWH enrolled in HIV care, 49,375 (28%) were ART-eligible at enrollment, and 36,508 of ART-eligible (74%) initiated ART. Of all PLWH, 5,014 (3%) had TB at enrollment. PLWH with TB at enrollment had a higher median CD4+ count than ART-eligible PLWH without TB (189 vs. 140 c/mL; p<0.001). Median time to ART initiation for PLWH with TB at enrollment decreased from 55 and 56 days before to 28 and 43 days after WHO guidelines adoption in MZ (p<0.001) and RW (p= 0.015), respectively. In MZ, PLWH with TB had a longer time to ART initiation vs. ART-eligible PLWH without TB prior to WHO guidelines adoption (p<0.001) but a shorter time to ART initiation after guidelines adoption (p<0.001). PLWH with TB at enrollment had a longer time to ART initiation vs. ART-eligible PLWH without TB both before and after WHO guidelines adoption in RW (p<0.001).
Conclusions: In this large cohort, adoption of WHO guidelines was associated with a shorter time to ART initiation for PLWH with TB in MZ and RW. However, as date of TB treatment initiation was not available, time from TB treatment initiation to ART initiation was not assessed. Further efforts are needed to more promptly initiate ART for eligible PLWH, particularly those with TB.

**Antiretroviral Therapy Initiation and Tuberculosis (TB) Risk in the United States (US) and Canada**

April Pettit1, Adell Mendes2, Sonia Napravnik2, Aimee Freeman1, Bryan Shepherd1, David Dowdy2, Anita Rachlis2, Richard Moore2, Timothy Sterling1, for the North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD)

1Vanderbilt University, Nashville, TN, United States, 2Johns Hopkins University, Baltimore, MD, United States, 3University of North Carolina, Chapel Hill, NC, United States, 4Sunnybrook Health Sciences Center, Toronto, ON, Canada

**Background:** Among HIV-uninfected persons in the US, TB incidence is ~ 3/100,000 person-years (p-y). Previous studies of HIV-infected persons in the US have found rates of ~200/100,000 p-y while on highly active antiretroviral therapy (HAART) and >700/100,000 p-y while not on HAART. HAART decreases TB risk over the long-term, but TB incidence is high shortly following HAART initiation. Previous studies have not assessed TB risk before and after HAART initiation in the same large population of HIV-infected persons from the US and Canada, and therefore both the short- and long-term effects of HAART on TB risk in this population.

**Methodology:** We conducted an observational cohort study among HIV-infected persons in the North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD) from 1998 through 2011. Data were contributed by 11 cohorts and patients were included if they had > 2 visits within 12 months. Person-time was contributed from enrollment in NA-ACCORD until first TB diagnosis, loss to follow-up, death, or administrative censoring. TB cases diagnosed after enrollment were included and were defined as culture-confirmed or culture-negative according to Centers for Disease Control and Prevention guidelines. TB diagnosis and diagnosis date were validated via standardized abstraction forms.

**Results:** Among 29,660 HIV-infected patients (158,293 p-y of follow-up), 164 TB cases (102 culture-confirmed, 64 culture-negative) were diagnosed (104/100,000 p-y; 95% CI 88-121/100,000 p-y). Median follow-up was 4.1 years (IQR: 1.8-7.6 years). TB incidence varied according to time from HAART initiation (Table).

**Conclusions:** In this large North American cohort, TB incidence before HAART initiation was lower than previously described. Consistent with previous studies, TB incidence was highest during the first 6 months following HAART initiation. TB incidence declines after 6 months of HAART exposure, but still exceeds that of HIV-uninfected persons even after 4 years on HAART. This highlights the continued need for vigilance for TB among HIV-infected persons, particularly shortly following HAART initiation.
Cryptococcal Disease

834 Prevalence of Cryptococcal Antigen Positivity Among AIDS Patients, United States From 1986-2012

Jennie L. McKenney1, Sean Bauman2, Brandon Neary3, Roger Detels1, Audrey French4, Joseph Margolick5, Jeffrey D. Klausner6

1Epidemiology, University of California, Los Angeles, Los Angeles, CA, United States; 2Immuno-Mycologies, Inc., Norman, OK, United States; 3Immuno-Mycologies, Inc., Norman, OK, USA; 4Infectious Diseases, John H. Stroger, Jr. Hospital, Chicago, IL, United States; 5Molecular Microbiology and Immunology, Johns Hopkins University, Baltimore, MD, United States; 6Infectious Diseases, University of California, Los Angeles, Los Angeles, CA, United States

Background: Cryptococcal meningitis (CM) is the most common cause of AIDS-related mortality in sub-Saharan Africa. CM accounts for between 33% and 63% of all adult meningitis within that region and is responsible for over 500,000 deaths annually; more AIDS-related deaths than tuberculosis. In sub-Saharan Africa, the WHO recommends routinely screening AIDS patients with a CD4 T-cell count less than 100 cells/μl for cryptococcal infection and initiating anti-cryptococcal therapy to prevent CM. The prevalence at which routine cryptococcal infection was found to be cost-effective was 2%. In the United States however there are no such screening recommendations because there is a lack of prevalence data and thus no opportunity for a cost-effective analysis. We aimed to determine the prevalence of cryptococcal infection among advanced AIDS patients in the United States to guide potential updates in the prevention and management of CM.

Methodology: Using stored sera from the Multicenter AIDS Cohort Study and the Women’s Interagency HIV Study, we screened specimens from 1,872 participants with CD4 T-cell counts less than 100 cell/μl for cryptococcal infection. We tested serum from participants using the CrAg Lateral Flow Assay (Immy, Inc. Norman, OK), a FDA-cleared test for the detection of cryptococcus antigen (CrAg).

Results: The overall prevalence of CrAg positivity within this population was 2.9% (CI: 0.2-3.8%). The table below describes the results of CrAg positivity by gender, geographical location, and time (pre-HAART and post-HAART). Due to restrictions in table length, Baltimore (3.0%, CI:1.5-6.0%), Chicago (2.3%, CI:0.8-6.8%), and Brooklyn (1.9%, CI:0.6-5.3%) were not included in the table below.

Conclusions: Presently, routine screening for cryptococcal infection is only recommended in AIDS patients with a CD4 less than 100 cell/μl in sub-Saharan Africa. The results from this study suggest the prevalence of cryptococcal infection in the United States is above published cost-effective threshold, varies regionally and may warrant routine screening to detect early infection.
835  **High Prevalence of Undiagnosed *Cryptococcus* at HIV Diagnosis Across the CD4 Spectrum in Durban**

Paul K. Drain¹, Julia M. Kleene², Elena Losina³, Sharon M. Coleman⁴, Janey Giddy⁵, Douglas Ross⁶, Jeffrey Katz⁷, Rochelle P. Walensky⁸, Kenneth A. Freedberg⁹, Ingrid V. Bassett¹⁰

¹Massachusetts General Hospital; Harvard Medical School, Boston, MA, United States, ²Stony Brook School of Medicine, Stony Brook, NY, United States, ³Boston University School of Public Health, Boston, MA, United States, ⁴McCook Hospital, Durban, South Africa, ⁵St. Mary’s Hospital, Durban, South Africa, ⁶Brigham and Women’s Hospital, Harvard Medical School, Boston, MA, United States

**Background:** Early detection and treatment of cryptococcal antigen (CrAg) may decrease morbidity and mortality from cryptococcal meningitis. Based on World Health Organization guidelines, South Africa recommends screening all HIV-infected people with CD4 <100/mm³ for CrAg. The prevalence of cryptococcal infections across varying CD4 counts has not been reported at initial HIV diagnosis. We sought to assess the prevalence of cryptococcal infections, stratified by CD4 count, among newly diagnosed HIV-infected adults attending outpatient clinics in Durban.

**Methodology:** We enrolled newly-diagnosed HIV-infected adults into a prospective study between October 2011 and January 2013. Participants were recruited from 4 outpatient sites offering HIV testing services, including an urban hospital, a peri-urban hospital, and 2 municipal peri-urban primary health clinics. Eligible participants were ≥18 years old, newly-diagnosed with HIV, not receiving antiretroviral therapy, and initially seeking outpatient care for a variety of complaints. Participants provided a urine specimen in a sterile container that was stored in a -20 °C freezer for later testing. We performed CrAg testing with the rapid CrAg lateral flow assay (Immy Inc., Norman, OK; estimated 98% sensitivity on urine specimens) according to the manufacturer’s specifications. We assessed CrAg prevalence for a difference above/below CD4 100/mm³ (primary analysis), and above/below CD4 200/mm³ (secondary analysis).

**Results:** Among 773 participants, mean age was 34.4 years, and 41% were female. Overall CrAg prevalence was 10.1% (95% CI 8.0-12.2%), and was not significantly associated with age or gender. CD4 count was available for 660 (85%) participants; median CD4 count was 210/mm³ [Interquartile Range (IQR) 80-358/mm³]. Participants with CD4 >100/mm³ had an estimated CrAg prevalence of 9.9% (95% CI 7.2-12.6%), which was not significantly different from those with CD4 ≤100/mm³ (8.7%; 95% CI 4.7-12.6%). Similarly, participants with CD4 >200/mm³ had an estimated CrAg prevalence of 14.7% (95% CI 10.5-19.0%), which was significantly higher than those with a CD4 ≤200/mm³ (7.5%; 95% CI 4.6-10.4%). Median CD4 count was 249/mm³ (IQR 83-445/mm³) among CrAg-positive participants, and 203/mm³ (IQR 80-352/mm³) among CrAg-negative participants.

**Conclusions:** Prevalence of cryptococcal infection at the time of HIV diagnosis is high in Durban. Our data suggest there is little difference in those designated as high risk versus low risk for cryptococcal infection using the current CD4 count screening criteria. Therefore, the screening recommendation should be reexamined as it misses many cryptococcus-infected people.

836  **Monocyte Dysfunction Is Associated With 14-Day Mortality in Cryptococcal Meningitis**

James Scriven¹, Lisa Graham¹, Charlotte Schutz¹, Robert Wilkinson², Britta Urban³, Graeme Meintjes¹, David Lalloo²

¹Institute of Infectious Diseases and Molecular Medicine, University of Cape Town, Cape Town, South Africa, ²Liverpool School of Tropical Medicine, Liverpool, United Kingdom

**Background:** Cryptococcal meningitis (CM) remains a significant cause of death amongst individuals with HIV-1 infection. Immune correlates of protection are lacking. Animal and in vitro studies suggest macrophage and monocyte activation plays a key role in determining outcome from infection. This study examines the relationship between peripheral blood monocyte activation and clinical outcome in patients with HIV-1-associated CM.

**Methodology:** Patients with HIV-1-associated CM were recruited from hospitals in Cape Town. Initial anti-fungal therapy was IV amphotericin 1mg/kg and oral fluconazole 800mg per day. Monocyte sub-populations and their activation phenotype were characterized in whole blood at baseline using flow cytometry. Intracellular cytokine responses were assessed following 6-hour stimulation with lipopolysaccharide (LPS) and R848 (TLR7/8 agonist). Comparisons in baseline monocyte activation were made between subjects who survived to 14 days and those who died.

**Results:** 59 subjects were enrolled, median CD4 count was 34x10⁶/ml and 14-day mortality was 24%. Compared to survivors (S), non-survivors (NS) had significantly lower expression of HLA-DR, and significantly higher expression of CD163, on CD14+CD16+ monocytes at baseline (mean HLA-DR MFI 7272 [S] vs 4197 [NS]; mean CD163 MFI 10541 [S] vs 17420 [NS]; p=0.007 and p=0.03 respectively). In addition, following LPS stimulation monocyte %TNFα +ve Mo R848 stimulation (mean, 95%CI) 68.1[60.0-76.3] 64.7[53.1-76.4] 0.66, and CRP (median, IQR) 34.7 (12.73-67.33) 84.9 (39.3-119.8) 0.01, were significantly different between survivors and non-survivors.

**Conclusions:** This study suggests impaired monocyte function may be an important factor determining poor outcome in cryptococcal disease. This may reflect overstimulation, and compensatory down-regulation, of inflammatory responses in circulating monocytes. Reversal of this defect may be a potential immune-based therapeutic strategy.

Serum Biomarkers Following Induction Therapy for Cryptococcal Meningitis Predict Survival

**Joshua Rhein,** James Schrenzi, Kathy Huppler Hulsiek, Maximilian von Hoenberger, David B. Meya, Conrad Muzoora, Graeme Meintjes, David R. Boulware, COAT Trial Team

1University of Minnesota, Kampala, Uganda, 2Liverpool School of Tropical Medicine, Cape Town, South Africa, 3University of Minnesota, Minneapolis, MN, United States, 4Infectious Disease Institute, Kampala, Uganda, Mbarara University of Science and Technology, Mbarara, Uganda, 5University of Cape Town, Cape Town, South Africa

**Background:** In the Cryptococcal Optimal ART Timing (COAT) trial, early ART initiation (7-13 days) after cryptococcal meningitis (CM) was associated with higher mortality compared with deferred (5 weeks) ART initiation. A significant proportion of deaths (70%, 49/70) occurred after completion of 14 days of amphotericin induction therapy. We hypothesized that serum biomarkers may enable risk stratification of short and long term mortality.

**Methodology:** 177 COAT subjects were randomized in Kampala and Mbarara, Uganda and Cape Town, South Africa. 156 participants survived to the end of amphotericin therapy of which 153 had 22 serum biomarkers profiled using ELISA or Luminex multiplex assay. We compared by logistic regression log2-transformed biomarkers versus 5 week survival (i.e. time of outpatient clinic registration) and 46 week survival, adjusting for randomized arm (early ART vs. deferred ART).

**Results:** Of 153 persons who survived 14 days after cryptococcal meningitis diagnosis, 121 (81%) survived for 5 weeks until time of outpatient clinic registration and 104 (68%) survived >1 year. Twelve serum biomarkers were associated with increased risk of mortality. Odds Ratio (OR) for mortality for each two-fold increase in serum biomarker is presented in the Table. Serum CRP was a consistent risk factor for short and long term mortality. Additionally, when CRP was measured at 21 days after diagnosis (2 weeks after randomization), CRP was associated with mortality between 3-5 weeks (OR 2.22 per 2-fold increase 95%CI: 1.35; 3.66, P=0.0002) as well as mortality through one year (OR 1.45 per 2-fold increase, 95% CI: 1.08; 1.95; P=0.01).

**Conclusions:** Serum biomarkers at the end of amphotericin induction therapy may enable risk stratification of short and long term mortality, most notably including CRP, a commonly available routine lab test. Through risk stratification, close clinical follow up may be wise for individuals who have survived their initial cryptococcal meningitis but remain at high risk of death.

Cryptococcal Antigenemia in Severely Immunocompromised HIV Patients in Rural Tanzania

**Matthias C. Müller, Alex J. Ntamatungiro, Namwua Kimera, Hansjakob Furner, Manuel Battegay, Marcel Tanner, Christoph Hatz, David R. Boulware, Tracy R. Glass, Emilio Letang**

1Swiss Tropical and Public Health Institute (Swiss TPH), Basel, Switzerland, 2Itakaka Health Institute (IHI), Itakaka, Mongoro, Tanzania, United Republic of, 3Division of Infectious Diseases, University Hospital Bern, Bern, Switzerland, 4Division of Infectious Diseases and Hospital Epidemiology, University Hospital Basel, Basel, Switzerland, 5Division of Infectious Diseases & International Medicine, Department of Medicine, University of Minnesota, Minneapolis, MN, United States

**Background:** Cryptococcal meningitis is a leading cause of death in people living with HIV/AIDS in sub-Saharan Africa. To decrease cryptococcosis, WHO recommends pre-antiretroviral (ART) targeted cryptococcal antigen (CrAg) screening for persons with CD4 < 100 cells/μL. Aiming to explore the potential impact of this strategy in Tanzania, we assessed the prevalence, natural course, and outcome of cryptococcal antigenemia in a rural region of southern Tanzania.

**Methodology:** Retrospective study including all patients prospectively enrolled in the Kilombero and Ulanga Antiretroviral Cohort (KIULARCO) with a pre-ART visit between Jan 1, 2007 and Dec 31, 2012. Cryopreserved pre-ART plasma samples of ART-naive patients > 5 years-old and with CD4 < 150 cells/μL were tested for CrAg using lateral flow assay kits. Logistic regression was used to estimate the association between CrAg+ and a composite outcome of death or lost to follow-up (LFU) after one-year follow-up.

**Results:** Of 801 eligible patients, 29 (3.6%) were CrAg+, corresponding to 6.1% (18/293), 2.3% (6/263), and 2% (5/245) prevalence among patients with CD4 < 50, 51-100, and 101-150 cells/μL, respectively. ART was initiated in 686 (85.6%). Within one year, 72.4% (21/29) of CrAg+ patients died or were LFU compared with 47.2% (364/772) of CrAg-negative patients (p=0.008), with no differences across CD4 strata. After adjusting for age and gender, three independent predictors of death/LFU were identified: CrAg+ (odds ratio (OR) 3.2, 95% confidence interval (CI) 1.4-7.3, p=0.008), CD4 < 50, 51-100, and 101-150 cells/μL, respectively. ART was initiated in 686 (85.6%). Within one year, 72.4% (21/29) of CrAg+ patients died or were LFU.

**Conclusions:** Risk stratification, close clinical follow up may be wise for individuals who have survived their initial cryptococcal meningitis but remain at high risk of death.
Fluconazole given at physician discretion decreased the proportion of death/LFU among CrAg+ patients (80% without treatment, 60% with 100-200 mg daily, and none with 800 mg daily, p=0.012).

Conclusions: CrAg+ was prevalent and an independent predictor of death/LFU. Targeted pre-ART CrAg screening may decrease early ART-mortality in Tanzania. However, a threshold for CrAg screening at CD4 < 100 cells/μL, according to WHO recommendations, may exclude a substantial number of CrAg+ patients and decrease the potential impact of this strategy.

839 HSV-2 Serostatus Is Not Associated With Inflammatory or Metabolic Markers in ART-Treated HIV
Darrell Tan1, Janet Raboud2, Leah Szadkowski3, Tae Joon Yi4, Brett Shannon4, Rupert Kauf4, W. Conrad Liles5, Sharon Walmsley3
1St. Michael’s Hospital, Toronto, ON, Canada, 2Toronto General Research Institute, Toronto, ON, Canada, 3University Health Network, Toronto, ON, Canada, 4University of Toronto, ON, Canada, 5University of Washington, Seattle, WA, United States

Background: Systemic inflammation and immune activation may persist in HIV-infected persons on suppressive antiretroviral therapy (ART) and contribute to adverse health outcomes. A randomized trial recently showed no impact of valacyclovir on inflammatory markers in this population, but the explanation for these negative findings is unclear. We compared markers of immune activation, inflammation, endothelial activation, and abnormal glucose and lipid metabolism in HIV-infected adults according to herpes simplex virus type 2 (HSV-2) serostatus.

Methodology: HIV-infected adults on suppressive (viral load <50 copies/mL) ART were categorized as HSV-2 seropositive or seronegative using the HerpeSelect ELISA (Focus), and underwent study visits at baseline, 3 and 6 months. The primary outcome was the median percentage of activated (CD38+HLADR+) CD8 T-cells. Secondary outcomes included additional immune (activated CD4, regulatory T-cells) and inflammatory (hsCRP, D-dimer, IL-1β, IL-6, MCP-1, TNF, sICAM-1, Ang1/Ang2 ratio) markers. Metabolic outcomes included the proportion with impaired fasting glucose/impaired glucose tolerance/diabetes, insulin sensitivity (Matsuda index), insulin resistance (HOMA-IR), and fasting lipids. The impact of HSV-2 on each outcome was estimated using generalized estimating equation regression models.

Results: Of 82 participants, 38 (45%) were HSV-2 seropositive. The HSV-2+ group included more black (32% vs 9%) and female (26% vs 2%) participants. Median (IQR) age, duration of HIV infection and baseline CD4 count were similar between groups, at 49 (43,53) years, 10 (7, 18) years and 466 (329, 622) cells/mm3, respectively. Most (60.7%) participants were current or former smokers. During the study, CD8 and CD4 T-cell activation declined by 0.16% and 0.08% per month respectively, while regulatory T-cells increased by 0.05% per month. However, HSV-2 serostatus was not associated with a difference in either the primary or secondary immune/inflammatory outcomes (Table; asterisks denote odds ratios of having detectable value), nor in metabolic outcomes, in univariate or multivariable models adjusted for time, sex, duration of HIV infection and baseline CD4 count.

Conclusions: HSV-2 serostatus was not associated with immune activation, inflammatory or lipid and glucose metabolic markers in this cohort of HIV-infected adults on suppressive ART. Whether differences might be seen in sub-populations of patients requires further study.

**Latent, Acute, or Neuro-Syphilis Does Not Increase HIV-1 Replication in Central Nervous System**

Maximilian Donath1, Timo Wolf2, Annette Haberl2, Markus Bickel2, Sri Göpel3, Annemarie Berger3, Dimitria Bon4, Claudia Brandt4, Christoph Stephani2

1Goethe University Hospital, Frankfurt, Germany, 2Infectious Diseases, Goethe University Hospital, Frankfurt, Germany, 3Medical Virology Institute, Goethe University Hospital, Frankfurt, Germany, 4Biomathematics, Goethe University Hospital, Frankfurt, Germany, 5Medical Microbiology Institute, Goethe University Hospital, Frankfurt, Germany

**Background:** Acute syphilis-infection was associated with blips, i.e. a timely limited HIV-1 virus load (VL)-increase, during otherwise suppressive antiretroviral therapy (ART), and the central nervous system (CNS) inflammation could be a virus reservoir. Purpose of this study was to explore if syphilis-co-infection leads to increased CNS-replication of HIV-1.

**Methodology:** Retrospective case-control study from a large German HIV-treatment unit, data were collected from 2005-2013; cerebrospinal fluid (CSF) was collected for various reasons in patients with or without neurological symptoms. Patients were eligible, if paired VL-results from simultaneous HIV-1 assessments in CSF and blood plasma were available, in addition to syphilis serology details, ART and clinical/demographic data; VL-ratio for CSF/blood was built for each patient. If TPPA-screening result was positive, further tests (VDRL, IgM, CSF/blood-antibody ratio) allowed patient grouping into latent, acute, or confirmed neuro-syphilis, enabling statistical evaluation of HIV-1 CNS-replication.

**Results:** 179 HIV-1 infected patients were evaluable: 123 control-patients with negative screening result, and 56 patients with positive TPPA; out of these, 18 had confirmed acute syphilis infection; among these, 10 had neuro-syphilis, as of CSF-evaluation result. In comparisons between syphilis seropositivites-subgroups, each versus controls, no significant difference for HIV-1 was found in CSF, blood and CSF/blood-ratio.

Positive syphilis serology affected predominantly males (91.1%, vs. controls: 70.7%; p=0.005). Patients were older at first positive HIV-test (p<0.001) and still at time of CSF-collection (p=0.003). Comparing all syphilis seropositives with controls for antiretroviral therapy, the rate receiving it was similar (61.0% vs. 59.3%), but lower for those with acute syphilis infection (35.3%, p<0.05 vs. controls; see Table).

**Conclusions:** HIV-1 replication in CSF, blood, and CSF/blood VL-ratio was not higher and not significantly different between patient groups with syphilis seropositive status, confirmed acute, or neuro-infection, respectively, and syphilis seronegative controls. This unselected cross-section study from a large treatment cohort could not support the hypothesis of a CNS reservoir for HIV-1 throughout different stages of syphilis infection. Patient characteristics are reflecting a high proportion of HIV-late presenters among those with acute syphilis disease.

**Results for HIV-1 infected patients with latent, acute and neuro-syphilis co-infection**

**Early Impact of cART On the Risk of Herpes Zoster: Results From the FHDH-ANRS CO4**

Sophie Grabar1, Pierre Tattevin2, Hana Selinger-Leneman4, Arnaud de la Blanchardière4, Christian Rabaud1, David Rey2, Vincent Danieluzzi1, Samuel Ferret4, Dominique Costagliola1, Odile Launay1

1INSERM U943, Paris, France, 2Hôpital Hôtel-Dieu, Unité Biostatistique et Épidémiologie, Université Paris Descartes, Paris, France, 3Hôpital Pontchaillou, Rennes, France, 4CHU Caen, Caen, France, 5INSERM U943, Nancy, France, 6CHU Strasbourg, Strasbourg, France, 7Hôpital Fourestier, Nanterre, France, 8Hôpital St Louis, Paris, France, 9Hôpital Cochin, Paris, France

**Background:** Recent studies evidenced a decrease in HZ incidence in the cART era, although HZ has been associated with the emergence of immune reconstitution inflammatory syndrome (IRIS). However evidences are lacking on large longitudinal data on the early impact of cART initiation on the risk of HZ.
Methodology: From the FHDH-Anrs CO4 cohort, we selected patients followed during years 1992-2011, naïve of ART treatment, who either initiated a cART or remained untreated. Risk of HZ according to the duration of cART (0-6, ≥6 months) was studied with Poisson regression with patients untreated during years 1996-2011 as reference. Crude and relative risks (RR) adjusted for demographics and with or without adjustment for CD4 and HIV RNA were computed.

Results: Overall, 48,616 patients initially ART-naïve were included: 2654 incident HZ occurred at a median CD4 cells count of 366/mm³ (iqr, 218-530). Of these, 1521 HZ occurred in patients on cART, of whom 379 (25%) during the first 6 months of cART. In cART naïve patients, HZ incidence was 1305/10⁵ PY prior 1996. After 1996, the incidence was 1617 /10⁵ in the first 6 months of cART, was maximal at 3 months of cART (2413/10⁵ PY) and declined to 1036/10⁵ PY after 6 months of cART. The crude risk of HZ was elevated in the first 6 months of cART with a RRcrude of 1.50 (95%CI, 1.35-1.68), and markedly decreased after 6 months, with a RRcrude of 0.49 (95%CI, 0.45-0.53). Adjustments for current CD4 reduced the risk close to 1 (RR=0.97 95%CI, 0.86-1.09) in the first 6 months, but additional adjustment on HIV RNA showed a persistent moderate increase (RR=1.23 95%CI, 1.07-1.09). Higher risk of HZ was associated with low CD4 and high HIV RNA levels, low CD4/CD8 rate and prior AIDS and age.

Conclusions: The risk of HZ increases in the first months of cART initiation but only moderately while it sharply decreases after 6 months of cART. The overall decrease in incidence after cART is probably related to immune restoration and virological control.

842 Antigen-Presenting Cells Ingest Malaria Parasites and Cause an Increase in HIV-1 Replication
Marika Orlov¹, Florin Vaida¹, Kathryn Williamson², Qianqian Deng¹, David Smith¹, Patrick Duffy³, Robert Schooley¹
¹School of Medicine, University of California San Diego, La Jolla, CA, United States, ²Seattle Biomedical Research Institute, Seattle, WA, United States, ³NIAID, NIH, Rockville, MD, United States

Background: An increasing body of evidence has demonstrated that bidirectional HIV-1/P. falciparum interactions enhance morbidity and mortality where both pathogens are endemic. Repeat bouts of malaria cause an increase in levels of HIV replication and accelerate CD4 cell decline. Increased levels of HIV-1 RNA persist well after parasites are cleared from peripheral blood following antimalarial therapy. The mechanisms contributing to this bi-directional interaction have not been fully elucidated.

Methodology: We developed a tissue culture system in which peripheral blood mononuclear cells (PBMCs) from healthy American donors were infected with HIV in vitro, and co-cultured with P. falciparum infected (iRBCs) or uninfected (uRBCs) red blood cells. HIV-1 production was assessed by quantifying HIV-1 p24 antigen by ELISA in culture supernatants 4, 6, 8 and 10 days after initiation of the co-cultures. In certain experiments T-cell subsets were affinity purified by depletion with antibody-coated magnetic beads. T-cell surface activation markers were assessed by flow cytometry after 24 or 48 hours. Cytokine concentrations were quantified in the supernatants using a multiplex ELISA.

Results: HIV replication increased in the presence of iRBCs compared to uRBCs (area under the curve comparisons 20.6 vs 18.2 respectively, p=0.0045) and was associated with increased CD4 activation as assessed by CD4 HLA-DR/CD38 double positive cells at 48 hours (p=0.001). Supernatants from these co-cultures showed increased production of TNF-α, INF-γ, MIP-1α, but not IL-6. Neutralizing antibodies to TNF-α but not IFN-γ decreased HIV production when TNF-α was neutralized (p=0.04) but not IFN-γ (p=0.37). Depletion of macrophages and dendritic cells reduced HIV production (p=0.0074). In one experiment, macrophages and dendritic cells that had been pre-incubated with iRBCs for 48 hours stimulated HIV production from PBMCs without the addition of iRBCs to the co-cultures. Hemozoin crystals were observed within the dendritic cells after co-cultivation with iRBCs.

Conclusions: iRBCs stimulate replication of HIV-1 by-activated CD4 cells in a TNF-α dependent manner following processing of malarial antigens by macrophages and dendritic cells. These results suggest that the persistent elevation of HIV-1 replication following treatment for acute bouts of P. falciparum malaria may be due, at least in part, to ongoing stimulation of CD4+ T cells by hemozoin loaded macrophages within lymphoid tissues.
**Incidence of AIDS-Defining Opportunistic Illnesses (ADOIs) Among Patients in North America**

Kate A. Buchacz1, Bryan Lau2, Yuehou Jing2, Stephen J. Gange2, John T. Brooks1

1Centers for Disease Control and Prevention, Atlanta, GA, United States, 2Johns Hopkins University, Baltimore, MD, United States

**Background:** It is not clear if the rates of AIDS-defining opportunistic illnesses (ADOIs) have continued to decline or have stabilized in the recent era of combination antiretroviral therapy (cART) and what ADOIs now occur among HIV-infected North American patients who are in care and have no history of clinical AIDS.

**Methodology:** We studied 63,088 HIV-infected patients followed in 14 participating cohorts in the North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD) in the U.S. and Canada during 2000-2010. We excluded 13,784 (21.8%) patients who had any pre-existing ADOIs, and analyzed data for the remaining 49,304 patients regardless of their immunologic status. We calculated incidence rates per 100,000 person-years with 95% confidence intervals (CIs) based on Poisson distribution for the first occurrence of any ADOI, and for the first occurrence of select ADOIs thought to be well ascertained in the participating cohorts within three calendar periods: 2000-2003, 2004-2007, and 2008-2010.

**Results:** Of 49,304 patients analyzed (median [interquartile range] age at baseline = 40 [34-47] years, median CD4 at baseline = 370 [201-569] cells/mm3), 76% were men, 38% were white, 42% were black, and 19% were injection drug users; 6% were Canadian. The 49,304 patients contributed 196,284 person-years of observation, of whom 7,310 (14.8%) developed at least one ADOI. The incidence rates of ADOIs fell over time (all p<0.001) (Table), coincident with increasing use of cART and improvements in CD4 cell counts and HIV viral load suppression in the population (all p<0.001). During 2008-2010, the leading ADOIs included Pneumocystis jiroveci pneumonia, esophageal candidiasis, Kaposi’s sarcoma, and disseminated Mycobacterium avium complex or Mycobacterium kansasii.

**Conclusions:** We observed persistent reductions in incidence rates of ADOIs among HIV-infected patients in care during 2000-2010, which coincided with the improvements in viral suppression and immune status of the population. On average, among contemporary North American patients with no history of clinical AIDS, fewer than 3 in 100 develop any ADOI per year.

**Depot-Medroxyprogesterone Acetate Does Not Increase Genital SHIV Shedding in Macaques**

Jessica Radzio1, Krzyszta Hanley1, Debra Hanson1, James Mitchell1, Leecresia Jenkins1, Shanon Ellis1, Frank Deyounks1, Walid Heneine1, J. Gerardo Garcia-Lerma1

1Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States, 2Pathology, Emory University, Atlanta, GA, United States

**Background:** Epidemiologic studies in women remain inconclusive on whether the injectable contraceptive DMPA increases mucosal HIV shedding and transmissibility. We recently identified a low 3 mg DMPA dose that suppresses ovulation in pigtail macaques and recapitulates plasma MPA exposure and changes in vaginal epithelial thickness seen in women. Here we used this dose to assess the impact of DMPA on acute SHIV viremia and genital virus shedding.
Methodology: Twelve female pigtail macaques were infected vaginally with SHIV162p3 during their normal menstrual cycle (n = 6) or during monthly cycles with 3 mg of DMPA (n = 6). Plasma progesterone and medroxyprogesterone acetate (MPA) concentrations were measured weekly. SHIV RNA was quantified in plasma, rectal, and vaginal secretions by RT-PCR. Secretions were collected in sponges and evaluated for hemoglobin content to correct for plasma-derived viruses originating from blood contamination. Peak plasma viral load and RNA area under the curve values (AUC0-12wk) in DMPA-treated and untreated animals were compared using the Wilcoxon rank sum test. Viral shedding was compared using logistic regression with robust variances while controlling for temporal differences among macaques.

Results: Plasma MPA levels peaked 2-3 weeks after each dose, with mean concentrations (2.7 ng/mL; min, max = 1.4-4.8 ng/mL) that fell within the range seen in women receiving 150 mg of DMPA (2.5 ng/mL; range 1.6-3.3). Progesterone was undetectable in plasma during all 4-week DMPA cycles. Peak plasma viremia was similar in DMPA-treated and untreated macaques (6.7x10^6 copies/mL and 1.4 x 10^6 copies/mL, respectively; p=0.94). RNA AUC0-12wk values were also similar among treated and untreated macaques (means 1.9 x 10^6 and 7.0 x 10^6 RNA copies/day/mL, respectively, p = 0.94), although DMPA-treated macaques had higher odds of having virus being detected in plasma relative to controls (OR=6.6, p=0.022). Virus shedding did not differ for treated and untreated macaques in either rectal (p = 0.72) or vaginal (p = 0.53) secretions.

Conclusions: By using a pigtail macaque model that reproduces the effect of DMPA in women we observed little or no effect of DMPA treatment on acute SHIV viremias, genital, and rectal virus shedding. The lack of effect of DMPA on genital virus shedding does not support increased HIV transmissibility in women using DMPA and suggest non-biological explanations for the differences observed in some clinical and epidemiologic studies.

845 Dysregulation of Estradiol Signaling Contributes To Mucosal Barrier Dysfunction HIV+ Women

Sumathi Sankaran-Walters1, Anne Fenton1, Chris Gaulke1, Lauren Nagy1, Irina Grishina2, Jason Flamm2, Thomas Prindiville1, Satya Dandekar1

1Medical Microbiology and Immunology, University of CA, Davis, Davis, CA, United States, 2Internal Medicine, Kaiser Permanente, Sacramento, CA, United States, 3Internal Medicine, University of CA, Davis, Sacramento, CA, United States

Background: HIV infection is a leading cause of death in women in Africa. HIV disease progression correlates with immune activation which is higher in women compared to men in both the blood and gut. Compromised mucosal integrity allows for increased microbial translocation in women which stimulates systemic immune activation. Estradiol improves epithelial integrity but its effects during HIV infection are unknown. The objective of this study was to identify the effects of HIV infection on estradiol signaling in the gut and its impact on gut epithelial integrity.

Methodology: HIV+ women (n=9) and men (n=12) and HIV- healthy age matched women (n=7) and men (n=7) men were enrolled following IRB approved protocols. Small intestine mucosal samples were obtained by upper GI endoscopy. We compared gene expression profiles in gut epithelium, using laser capture microdissection and gene expression arrays. Plasma levels of microbial products in participants were assayed by real-time PCR. Immunophenotypic analysis was performed using 12 color flow cytometry. The effect of estradiol replacement and HIV infection on epithelial integrity was assayed using 3-D in vitro culture systems.

Results: A greater proportion of HIV+ women on HAART had sustained levels of GALT CD4+ T-cell activation (37.4% vs. 6.5%) and CD8+ T-cell activation (42.7% vs. 12.52%) than men (p<.05) measured by the expression of the surface marker HLA-DR. HIV+ women with and without HAART had lower levels of estrogen receptor β in the jejunum compared to healthy age matched controls. Comparison of gene expression in isolated epithelial cells showed down-regulation of epithelial regeneration pathways and tight junction proteins postmenopausal women associated with an increase in epithelial inflammation compared to premenopausal HIV+ women and men on HAART. Indicators of microbial translocation, such as plasma LPS, and bacterial 16S rRNA, were increased in women compared to men on HAART.

Epithelial cells grown in the presence of βE2 had increased proliferation (up to 40% higher) in a dose-dependent manner. Epithelial integrity measured by the trans-epithelial resistance (TER) also decreased by 25% in the presence of SIV infection. Low basal levels of exogenous BE2 restored the TER and increased expression of the tight junction protein, ZO1

Conclusions: These data suggest that increased inflammation secondary to microbial translocation may explain why women, especially postmenopausal women, have sustained CD4+ T-cell activation, despite effective control of viral replication. The decreased expression of ERβ may be a mechanism involved in this effect. Studies investigating the effects of HAART in women should focus on the role of hormones in the maintenance of mucosal integrity and health following menopause.

846 Hormonal Contraceptives Increase Innate Immune Effector Molecules in Cervicovaginal Secretions

Brandon L. Guthrie1, Robert Y. Choi2, Alison C. Robsey1, Rose Bosire3, Barbara Lehman-Payne1, Taha Hirbod2, Carey Farquhar2, Kristina Broliden4

1Department of Global Health, University of Washington, Seattle, WA, United States, 2Department of Medicine, University of Washington, Seattle, WA, United States, 3Department of Medicine Solna, Karolinska Institutet, Stockholm, Sweden

Background: Long-acting injectable hormonal contraceptives, most commonly in the form of depot medroxyprogesterone acetate (DMPA), are inexpensive and easy to use, but may be linked to increased risk of HIV acquisition. Cationic polypeptides are the principal effector molecules of the innate immune response in the vaginal mucosa, and higher levels of some polypeptides have been associated with increased risk of HIV infection. We hypothesize that DMPA modifies the innate immune response in the vaginal mucosal by increasing cationic polypeptides, contributing to the association between DMPA and HIV risk.

Methodology: We recruited HIV-1-exposed seronegative (HESN) women from HIV-discordant relationships and low-risk control women from discordant negative relationships in Nairobi, Kenya. Cervicovaginal lavage (CVL) samples were collected and enzyme-linked immunosorbent assays (ELISA) were used
to measure cationic polypeptide concentrations. Cervicovaginal IgA was assessed for HIV-1-neutralizing activity by a peripheral blood mononuclear cell-based assay using an HIV-1 clade A primary isolate.

Results: Among 160 HESN women and 73 low-risk control women, 169 (73%) reported not using hormonal contraception at enrollment, 41 (18%) used DMPA, 16 (7%) used an oral contraceptive, and 7 (3%) used an implantable form of hormonal contraception. There were no differences between HESN and control women in their levels of human neutrophil peptides 1-3 (HNP1-3) (p=0.445) or LL-37 (p=0.512). Combining HESN and low-risk control women, compared to women not using hormonal contraception, DMPA users had significantly higher mean levels of HNP1-3 (2.38 vs. 2.05 log$_{10}$ ng/ml; p=0.024) and LL-37 (0.84 vs. 0.48 log$_{10}$ ng/ml; p=0.026). These associations did not differ between HESN and control women (p=0.639). DMPA use was not associated with levels of secretory leukocyte protease inhibitor (SLPI) (p=0.776).

Conclusions: We found that HNP1-3 and LL-37 cationic polypeptides were elevated in the CVL fluid of HIV-1 seronegative women using DMPA, regardless of HIV-1 exposure. While these polypeptides have intrinsic antiviral capacity, they are also potent recruiters of target cells for HIV infection. As a result, higher levels of HNP1-3 and LL-37 have been associated with increased HIV infection risk. A potential mechanism for the risk associated with injectable hormonal contraceptive use may be through upregulation of these polypeptides in the vaginal mucosa, resulting in recruitment of dendritic cells that are susceptible to HIV infection. This may provide independent evidence supporting a biological mechanism for increased HIV acquisition seen with DMPA.

847 Injectable Contraception and HIV Acquisition in the VOICE Study (MTN-003)

Lisa M. Noguchi1, 2, Barbra Richardson3, Z. Mike Chirenje4, Gina Ramjee5, Gonasagrie Nair6, Thesia Palane6, Pearl Selepe6, Ravindre Panchia6, Kailazarid Gomez7, 8, Jeanne Marrazzo9, 10, on behalf of the VOICE Study Team

1Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, 2Microbicide Trials Network, Pittsburgh, PA, United States, 3SCHARP, Seattle, WA, United States, 4UZ-UCSF, Harare, Zimbabwe, 5MRC, Durban, South Africa, 6CAPRISA, Durban, South Africa, 7WITS Reproductive Health and HIV Institute, Johannesburg, South Africa, 8Aurum Institute, Klerksdorp, South Africa, 9PHRU, Soweto, South Africa, 10FHI 360, Durham, NC, United States, 11University of Washington, Seattle, WA, United States

Background: Injectable contraception constitutes a large proportion of modern contraceptive use globally. Several observational studies have reported an increased risk of HIV acquisition among women using depot medroxyprogesterone acetate (DMPA) compared to women using non-hormonal methods. Previous analyses have used a comparator group not on hormonal contraception (HC), and few have disaggregated use of norethisterone enanthate (NET-EN), another commonly used injectable method in South Africa.

Methodology: MTN-003 was a multi-site, randomized trial of oral and topical tenofovir-based HIV chemoprevention in women. Participants using effective contraception (HC, intrauterine device or sterilization) were eligible for enrollment. Contraceptive use and pregnancy and HIV status were assessed monthly during follow-up. Using a Cox proportional hazards model stratified by study site and censoring for pregnancy, we directly compared rates of HIV acquisition between women using DMPA and those using NET-EN in 11 South African MTN-003 sites.

Results: Among 4,077 participants, 3,167 women used injectable contraception during the study, of which 1,801 (56.9%) exclusively used DMPA, 1,109 (35.0%) exclusively used NET-EN and 257 (8.1%) used both DMPA and NET-EN during follow-up. Although DMPA and NET-EN users had similar rates of sexually transmitted infection at baseline, compared to NET-EN users, DMPA users were more likely to be over 25 (55.7% vs. 48.4%; p<0.001), married (5.7% vs. 3.7%; p<0.04) and have ≥ one child (93.5% vs. 69.8%; p<0.001). Distribution of injectable method types and HIV incidence differed by site (proportion of DMPA, 26.9% to 73.4%; HIV incidence, 1.7 to 9.3/100 person-years [p-yrs]). Among users of injectable contraception, 246 acquired HIV for an overall rate of 6.6 events/100 p-yrs. Rates of HIV-1 acquisition among women currently using DMPA and NET-EN during follow-up were 7.86 and 5.34/100 p-yrs, respectively (unadjusted hazard ratio [HR] 1.31, 95% CI 0.96 to 1.79, p=0.092; adjusted for age and marriage [aHR] 1.44, 95% CI 1.05 to 1.98, p=0.024). Restricting analysis to women under 25 found a similar but non-significant estimate (aHR 1.55, 95% CI 0.99 to 2.32, p=0.055).

Conclusions: Among women willing to use effective contraception while participating in an HIV prevention trial, there was an increased risk of HIV acquisition among women currently using DMPA compared to those using NET-EN. However, lack of a non-HC comparator group prevents estimation of risk associated with either method compared to non-use. Site differences in distribution of methods and HIV incidence may have impacted these results. Our findings support current WHO recommendations that women using injectable progestin contraception should be advised to use condoms.

HIV in Women: Pregnancy, Progression, Pap, and Bones

848 Rapid Disease Progression in HIV-1 Subtype C Infected South African Women

Nigel J. Garrett1, Lise Werner2, Koleka Millsana3, Lyle McKinnon3, Francois van Loggerenberg3, 1, Thambi Ndung’u2, Clive Gray4, Lynn Morris5, Carolyn Williamson5, Salim Abdool Karim1, 2

1CAPRISA, Durban, South Africa, 2Department of Medical Microbiology, University of KwaZulu-Natal, South Africa, 3The Global Health Network, University of Oxford, United Kingdom, 4HIV Pathogenesis Programme, Durban, South Africa, 5Institute of Infectious Diseases and Molecular Medicine, Cape Town, South Africa, 6Centre for HIV and STIs, Johannesburg, South Africa, 7University of Columbia, New York City, NY, United States

Background: While disease progression to AIDS has been estimated as approximately 10 years in HIV clade B infected cohorts, limited data exists from South Africa. An accurate description of the disease progression spectrum has important policy implications for the provision of antiretroviral therapy (ART). This study examines risk factors for rapid progression in a cohort of women followed from acute clade C infection and establishes proportions of women requiring ART at CD4 thresholds of <350 or <500 cells/µl.
**Methodology:** HIV uninfected women from seroincidence cohorts (n=839) at two sites in KwaZulu Natal (KZN) were assessed for acute HIV infection monthly (n=245) or 3 monthly (n=594) for up to 4 years. Those diagnosed with acute infection by HIV antibody (Ab) and PCR tests were followed prospectively. Rapid disease progression was defined as reaching a CD4 count of <350 or <500 cells/μl by 2 years post infection. Serial clinical and laboratory assessments were compared using survival analysis and logistic regression.

**Results:** Sixty-two women, median age 25 (IQR 21-33), were identified at median 42 days post infection (IQR 34-59), and contributed 282 women years of follow up. CD4 decline was rapid, with 31%, 44%, and 55% reaching <350 cells/μl at 1, 2 and 3 years post infection. This decline was even more dramatic using the <500 cells/μl cut-off, with 69%, 79% and 81% reaching this endpoint during the same timeframe (Figure 1). Multivariate predictors of progression to CD4 count <350 at 3 months post infection were CD4 count \[\text{adjusted hazard ratio (aHR)} 1.96 \text{ per 100 cells; 95\% CI 1.22-3.15; } p=0.006\] and viral load \[\text{aHR } 3.79 \text{ per log10 copies; 95\% CI 1.38-10.37; } p=0.010\], prevalent hepatitis B core Ab positivity \[\text{aHR } 4.58; 95\% CI 1.14-18.35; \text{p}=0.032\] and presence of protective HLA-B type alleles \[\text{aHR } 0.18; 95\% CI 0.05-0.73; \text{p}=0.016\]. Three women with incident hepatitis B infection all progressed rapidly.

**Conclusions:** Rapid HIV disease progression is common among clade C infected women from KZN, South Africa, and could be predicted in early infection. Based on this study, the majority of women would qualify for ART if the CD4 threshold was increased to 500 cells/μl as per WHO guidelines. Given the high HIV incidence in KZN, the dual benefit of earlier ART to reduce transmission and improve individual health in a setting where rapid progression is the ‘norm’ provides a strong rationale for achieving greater ART coverage.

**Pregnancy Intentions Among HIV-Infected Women Seeking Antenatal Care in Cape Town, South Africa**

Tammy Phillips¹, Allison Zerbe², James McIntyre³, Greg Petro⁴, Elaine Abrams², Landon Myer¹

¹Division of Epidemiology & Biostatistics, University of Cape Town, Cape Town, South Africa, ²ICAP, Columbia University, New York, NY, United States, ³Anova Health Institute, Johannesburg, South Africa, ⁴Division of Obstetrics & Gynaecology, University of Cape Town, Cape Town, South Africa

**Background:** Unintended pregnancies in HIV-infected women present an ongoing challenge to prevention of mother-to-child HIV transmission efforts, but data are mixed on whether use of antiretroviral therapy (ART) enhances women’s pregnancy intentions.

**Methodology:** We conducted a cross-sectional survey of consecutive HIV-infected women making their first antenatal care visit at a large primary care clinic in Gugulethu, Cape Town (antenatal HIV seroprevalence, 26%). A structured questionnaire was used to collect demographic and medical history; pregnancy intentions were assessed using the London Measure of Unplanned Pregnancy. Analyses compared three groups of women: those newly diagnosed with HIV on the day of the interview, those known to be HIV-infected, including those already on ART (n=203). Among women on ART, the median duration of ART use was 2.8 years (IQR, 1.4-5.2). Women who were newly diagnosed were younger and had a lower gravidity than women known to be HIV-infected, including those already on ART (p<0.001). The current pregnancy was significantly more likely to be reported as unintended by women who were newly diagnosed (57%) or known HIV-infected but not using ART (61%) compared to women already on ART (43%; global p-value, 0.007); this association was not confounded by demographic or socioeconomic measures (odds ratio from multiple logistic regression, 2.50; 95\% CI: 1.61-3.86).

Women on ART were also more likely to report discussing pregnancy with their partner and attempting to improve their own health before conception (p=0.003 and 0.024, respectively). In the subset of women on ART, there was no association between duration of ART use and pregnancy intention (p=0.077). Among women who reported an unintended pregnancy, 27% reported use of family planning at the time of conception.

**Conclusions:** Levels of unintended pregnancy in HIV-infected women are high overall, and there is a clear need for strengthened family planning services for HIV-infected women in this setting. Here, women on ART are more than twice as likely to plan their pregnancies as HIV-infected women not on ART, pointing to the impact of ART initiation on pregnancy intentions in this setting.
Table 1. Socio-demographic characteristics and measures of pregnancy intentions among 592 HIV-infected women making their 1st antenatal clinic visit in Cape Town, South Africa, by knowledge of HIV status / current ART use. All cells are N(%) unless otherwise specified.

850 Effect of Antiretroviral Regimens On Bone Mineral Density of HIV Infected Lactating Ugandan Women
Carolyne Onyango-Makumbi¹, Mike Mubiru¹, Prossy Ethel Namuli¹, Jane Ssebaggala¹, Joyce Matovu Namale¹, Mary Glenn Fowler², ²
¹Makerere University - Johns Hopkins University Research Collaboration, Kampala, Uganda, ²Johns Hopkins University, Baltimore, MD, United States

Background: During lactation, bone density (BD) decreases on average about 1% - 3% per month during and returns to prior levels after lactation stops. Among HIV infected individuals, ART may also cause serial decrements in BD over time. Thus, there could be potential synergistic effects among HIV infected women on ART who are also lactating, which could lead to accelerated decreases in BD during the breastfeeding period. Given the dearth of BD data in African populations, we evaluated BD measurements among postpartum HIV infected lactating women receiving ART.

Methodology: From February 2012 - October 2013, we studied BD measurements among lactating HIV infected postpartum women in Kampala, Uganda. Based on evolving prevention of mother-to-child transmission (PMTCT) of HIV/AIDS guidelines in Uganda, women received either zidovudine (ZDV) during pregnancy for PMTCT of HIV/AIDS followed by nevirapine prophylaxis to the infant (Option A) or highly active ART (HAART) for their health. From October 2012, lifelong ART was offered to all pregnant or breastfeeding HIV infected women regardless of CD4 count (Option B+). BD measurements using Dual Energy X-ray Absorptiometry were taken at 2 weeks and 9 months postpartum.

Results: 218 HIV infected lactating women were enrolled at delivery and followed through 9 months postpartum: 57 initiated Option A and 161 received Option B+ or HAART. Overall, median T-score for the spine at 2 weeks was -1.05 and at 9 months declined to -1.35 (p=0.0007). Median T-score for the hip at 2 weeks was 0.1 and at 9 months declined to 0.5 (p=0.0001). The median T-score of the spine in women who received Option A at 2 weeks...
was -1.55 compared with -1.00 in Option B+/HAART recipients (p=0.42). Median T-score of the hip in Option A recipients at 2 weeks was 0.25 compared with 0.1 in Option B+/HAART recipients (p=0.13). At 9 months, the median T-score of the spine in Option A recipients was -1.4 compared with -1.3 in Option B+/HAART recipients (p=0.84). Median T-score of the hip in Option A recipients at 9 months was -0.5: the same in Option B+/HAART recipients.

**Conclusions:** Significant decrements in BD were observed over 9 months post delivery in HIV infected and lactating women who received ART either for PMTCT or HAART. However, there were no significant differences in the reduction of BD among women who received antenatal ZDV (Option A) compared to women who received ART (Option B+/HAART).

### 851 Visual Inspection With Acetic Acid Is Good for Follow-Up After Cryotherapy in HIV-Infected Women

**Elkanah O. Omenge**¹, Peter M. Itsua², Tao Liu², Hillary Mabeya³, Astrid Christophersen-Deb³, Sierra Washington⁴, Susan Cu-Uvin⁵

¹Reproductive Health, Moi University School of Medicine, Eldoret, Kenya, ²Biostatistics, Brown University/The Miriam Hospital, Providence, RI, United States, ³Obstetrics and Gynaecology, University of Toronto, ON, Canada, Toronto, ON, Canada, ⁴Obstetrics and Gynaecology, Albert Einstein College of Medicine, Bronx, NY, United States, ⁵Obstetrics and Gynaecology, Brown University/The Miriam Hospital, Providence, RI, United States

**Background:** As See and Treat programs using VIA and cryotherapy gain popularity, the appropriate follow-up is critical. Few studies have addressed the optimal follow-up for HIV-infected women after VIA and immediate cryotherapy. This study seeks to identify the optimal follow-up test to accurately detect persistent moderate/severe cervical dysplasia and cancer in HIV-infected women who participated in a See and Treat program consisting of VIA, digital cervicography and immediate cryotherapy.

**Methodology:** We present preliminary data from 407 HIV-infected women who were evaluated with repeat VIA, conventional Pap smear, and High Risk HPV testing (hc2HPV DNA test) ± 6 months following VIA and immediate cryotherapy. Women who had abnormal testing on VIA, Pap smear (LSIL or worse), or HR HPV were scheduled for colposcopy and biopsy. Accuracy in detecting CIN II or worse was compared among these tests among 165 women with biopsy results.

**Results:** Median age was 35 yrs, 66% were WHO stage 1-2, median CD4 count was 410, 88% were on combination antiretroviral therapy. VIA agreed perfectly with both Pap and HR HPV tests in 154 women (38%; 95% CI=33-43%), or agreed with at least one of the two tests in 358 women (88%; CI=84-91%). VIA agreed with Pap and HR HPV testing in 73% (CI=69-78%) and 52% (CI=47-57%) of women, respectively. VIA had higher sensitivity (P=0.26) than Pap smear, lower sensitivity than HR HPV (P<0.01). VIA had lower specificity than Pap smear (P=0.23) but much higher specificity than HR HPV (P<0.01). Positive predictive value was 30.4%, 40.7% and 33.8%, for VIA, Pap smear, HR HPV, respectively (n=165).

We found that the disease negative rate after VIA and cryotherapy (negative VIA, normal Pap smear, negative HR HPV) at ± 6 months following VIA and immediate cryotherapy (n=358). VIA agreed perfectly with both Pap and HR HPV tests in 154 women (38%; 95% CI=33-43%), or agreed with at least one of the two tests in 358 women (88%; CI=84-91%). VIA agreed with Pap and HR HPV testing in 73% (CI=69-78%) and 52% (CI=47-57%) of women, respectively. VIA had higher sensitivity (P=0.26) than Pap smear, lower sensitivity than HR HPV (P<0.01). VIA had lower specificity than Pap smear (P=0.23) but much higher specificity than HR HPV (P<0.01). Positive predictive value was 30.4%, 40.7% and 33.8%, for VIA, Pap smear, HR HPV, respectively (n=165).

**Conclusions:** Follow-up with VIA agrees reasonably well with Pap smear and HR HPV tests. The disease negative rate after VIA and immediate cryotherapy was 85% among HIV-infected women in our study is less than previously reported for non-infected women (85-88%).

### 852 HIV Inhibition and Variation in Anti-Microbial Peptides Associated With Intercourse

**J. D. Fortenberry**¹, Mary A. M. Rogers², Krystle Fordyce², Steven R. King², David M. Aronoff², Sari M. Van Anders³

¹Pediatrics, Indiana University School of Medicine, Indianapolis, IN, United States, ²University of Michigan, Ann Arbor, MI, United States, ³Vanderbilt University, Nashville, TN, United States

**Background:** Anti-microbial peptides (AMP) in vaginal fluid play a key role in vaginal mucosal immunity but dynamic effects have not been documented. Since penile-vaginal intercourse (PVI) is an important HIV transmission route, variation in AMP levels could affect HIV inhibition and likelihood of infection. This study documents levels of several AMPs - trappin, human beta-defensin 2 (HBD2), lactoferrin, secretory leukocyte protease inhibitor (SLPI), and lysozyme - at the time of PVI (compared to a neutral control for time levels) and assesses effects on in-vitro HIV inhibition.

**Methodology:** 40 healthy women ages 18-39 years wore a vaginal tampon for 1 hour pre-PVI and again beginning 15 minutes after condom-protected PVI or during 1 hour of quiet time with a partner (without physical contact). Tampons were frozen in 1 ml of PBS at the subjects’ homes until processing. Vaginal AMP levels were assessed by commercially available ELISA assays and normalized to total protein to control for inter-sample dilutional variation. HIV-1 BaL was incubated in 10% vaginal fluid (PVI or quiet time) and used to infect TZM-bl indicator cells. Infectivity was measured by luciferase activity and % HIV inhibition calculated by normalizing to the activity in untreated controls. A random-effects logistic regression model was used to control for multiple within-person comparisons.
Results: Mean trappin levels were significantly greater at the time of PVI (1.99 mg/mg protein) versus quiet time (0.47 mg/mg protein; p=0.01) while mean levels of HBD2 (PVI = 136.36 ng/mg protein; quiet time = 265.16 ng/mg protein; p=0.04) and lactoferrin (PVI = 2.34 mg/mg protein; quiet time = 4.89 mg/mg protein; p=0.02) were significantly lower. Levels of SLPI and lysozyme did not significantly differ during PVI and quiet time. Controlling for PVI and menstrual phase, multivariable logistic regression showed that % HIV inhibition increased significantly with increased levels of HBD2 and lysozyme (p<0.001 and p=0.016, respectively).

Conclusions: PVI is associated with reductions in some vaginal AMP and these changes are associated with decreases in in-vitro HIV inhibition. These data describe a potential role for intercourse-associated changes in vaginal mucosal immunity that has implications for understanding of HIV infection as well as topical HIV prevention products such as microbicides.

853 Sex-Related Inflammatory Marker Changes Pre- and Post-ART Initiation

Jyoti S. Mathad1, Nikhil Gupta2, Ashwin Balagopal3, David Asmuth4, James Hakim5, Nagalingeswaran Kumaranasamy6, Thomas Campbell7, Judith S. Currier8, Susan E. Cohn9, Amita Gupta2, for the NWCS319 and ACTG 5175 PEARLS Study Teams

1Weill Cornell Medical College, New York, NY, United States, 2Johns Hopkins University School of Medicine, Baltimore, MD, United States, 3University of California Davis Medical Center, Sacramento, CA, United States, 4University of Zimbabwe College of Health Sciences, Harare, Zimbabwe, 5PRISCARE Medical Centre, Chennai, India, 6University of Colorado at Denver, Denver, CO, United States, 7David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, United States, 8Northwestern University Feinberg School of Medicine, Chicago, IL, United States

Background: Immune activation and inflammation are associated with HIV disease progression and death. Women, on average, have lower plasma HIV RNA (VL) early in infection but progress to AIDS at the same rate as men. Sex-specific differences in immune activation/inflammation pre- and post-ART initiation could explain these observed clinical differences, but this has not been well studied.

Methodology: Inflammatory/immune activation markers (IFN-γ, TNF-α, IL-6, IL-18, IP-10, CRP, LPS, sCD14, EndoCaib IgM, activated CD4/CD8) were measured pre-ART and at week 24 and 48 post-ART on a random sub-cohort from ACTG A5175 (PEARLS) comparing 3 ART regimens in 9 countries. Only those virologically suppressed on ART were included. We did a within-sex comparison of median marker levels between week 48 and baseline. Percent detection was used for LPS as many had no detectable LPS. To understand if women had more or less change in markers over time vs men, we performed multivariable longitudinal random effects modeling adjusting for age, country, BMI, baseline CD4, log10 VL, hemoglobin (Hb) and randomized ART arm.

Results: Samples were available for 125 men and 121 women. Women were younger (33 vs 36 years, p=0.01) and included more black subjects (64% vs 43%, p<0.001). At baseline-ART, women had higher median CD4 counts (195 vs 165 cells/mm3, p=0.01) and lower median VL (4.9 vs 5.1 log10 copies/mL, p=0.01) and Hb (11 vs 13 g/dL, p<0.001) than men. Women also had lower median CRP (2.1 vs 4.8 mg/L, p=0.002), percent detectable LPS (36% vs 53%, p=0.01), median sCD14 (1.8 vs 2.3 log10 pg/mL, p=0.009), and higher median EndoCaib (52 vs 45 MMU/mL, p=0.04) than men. At week 48, women had higher median IFN-γ (21 vs 13 pg/mL, p=0.04) compared to men.

Compared to baseline, men had lower levels of all inflammatory markers at week 48, except percent detectable LPS. Women also had decreases in TNF-α, IL-18 and IP-10, but had no change in IFN-γ, IL-6, and increased percent detectable LPS. In multivariate longitudinal analyses of changes over 48 weeks, women on average had a greater slope change in CD4 of 40 cells/mm3 (CI: 17-63, p=0.001), TNF-α of 3.3 ng/mL (CI: 0.16-6.3, p=0.04), but less of change in VL (0.31 log copies/mL, CI: 0.11-0.52, p=0.003), CRP (8 mg/L, CI: 2.4-13, p=0.005) and log10 sCD14 (3.8 log10 ng/mL, CI: 1.8-5.8, p<0.001) as compared to men.

Conclusions: Before ART, women had a more favorable immune profile with significantly higher CD4 and lower VL, CRP, detectable LPS and sCD14 than men. With ART, though, men experienced more of a decrease in inflammatory markers than women, erasing women’s initial advantage. This difference in response may explain why women progress to AIDS with lower viral loads. Further studies should investigate sex-specific differences in immune activation/inflammation pathways.

854 Influence of RAL vs Boosted ATZ-based Regimens On Cervical Immune Reconstitution and Activation

Amie L. Meditz1, Claire Palmer2, Julie Predhomme3, Kristina Searls1, Becky Kerr4, Patricia Caraway4, Edward M. Gardner4, Samantha MaWhinney2, Peter L. Anderson3

1Medicine, University of Colorado, Aurora, CO, United States, 2Biostatistics, University of Colorado, Aurora, CO, United States, 3Pharmacy, University of Colorado, Aurora, CO, United States, 4Denver Health Medical Center, Denver, CO, United States

Background: A significant amount of HIV-related morbidity has been attributable to genital tract disease in women. It is established that tenofovir (TDF), emtricitabine (FTC), and raltegravir (RAL) have high genital concentrations while atazanavir/ritonavir (ATZ) has more modest levels. We examine if RAL vs ATZ-based regimen is superior with respect to improved cervical immune reconstitution and less immune activation in HIV+ women.

Methodology: Peripheral blood (PB), cervical brush and lavage fluid (CVL), and cervical biopsies were collected from HIV+ women receiving TDF/FTC and either ATZ (n=19) or RAL (n=14). A history of CD4+ T-cells/mm3 (CD4) >= 300, and HIV RNA <48 copies/mL for a minimum of 6 months was required for entry. Cervical cells were analyzed by flow cytometry to determine %HLA-DR+CD38+(DR+38+) on CD4+ and CD8+T-cells. Sections of cervical biopsies were stained by immunohistochemistry and frequencies of CD3+CD4+, and CD3+CD8+cells per mm2 of tissue were determined using quantitative image analysis. RAL and ATZ trough concentrations in plasma and CVL were quantified with validated assays. T-tests, Fisher’s exact and linear regressions were used with log transformations as appropriate. Data are expressed as means or geometric means (CI).

Results: RAL and ATZ groups did not differ by age (46 vs 43 years, p=0.5), race (p=1.0), CD4 nadir (309 vs 340, p=0.65), current CD4 (663 vs 758, p=0.4) or PB CD4:CD8 ratio (1.0 (0.84, 1.18) vs 1.03 (0.78, 1.37), p=0.8). Years since HIV diagnosis and years on current ARV was significantly lower in women taking RAL vs ATZ (8 vs 13; p=0.03 and 2 vs 5; p=0.01, respectively). Plasma RAL vs ATZ levels were 121 (44, 335) vs 620 (419, 918) ng/
855 AMC 054: Safety and Immunogenicity of the Quadrivalent HPV Vaccine in Indian HIV-Infected Women

Joel Palefsky1, Selvamuthu Poongulali2, Shelly Lenseing3, Jeannette Lee1, Maria Da Costa4, Arunugham Jeena4, Syed Iqbal5, Nagalingeswaran Kumarasamy2
1University of California San Francisco, San Francisco, CA, United States, 2YRG Care Medical Centre, Chennai, India, 3University of Arkansas for Medical Sciences, Little Rock, CA, United States

Background: India has a high incidence of cervical cancer. HIV-infected Indian women may be at even higher risk than HIV-uninfected women. Quadrivalent HPV (qHPV) vaccination is effective in prevention of cervical cancer precursors due to HPV 6/11/16/18 in HIV-uninfected women. Little is known about safety and immunogenicity of qHPV in HIV-infected Indian women. Since the qHPV vaccine only prevents initial HPV infection, a high rate of prior exposure would render vaccination less effective. We performed a safety and immunogenicity study of the qHPV vaccine in Indian HIV-infected women. We also measured seropositivity to qHPV types and cervical HPV DNA positivity prior to vaccination.

Methodology: 150 HIV-infected women were enrolled at YRG Care Medical Centre, Chennai, India. At baseline we obtained CD4 level, HIV viral load, cervical cytology, colposcopy, HPV DNA and serology. HPV DNA was detected using MY09/11 primer PCR. Serologic geometric mean titers to HPV 6/11/16/18 were measured using a competitive Luminex immunoassay. Women were enrolled in one of 3 groups: Group 1: CD4 nadir ≤350 cells/mm3, on HAART, Group 2: CD4 nadir >350, current CD4 350-500, not on HAART, and Group 3: CD4 nadir >350, current CD4 >500, not on HAART. The qHPV vaccine was given at 0, 2 and 6 months. Serology was obtained at weeks 0, 28 and 52. Data on adverse events were collected at each visit.

Results: Mean age was 30.8 years (range, 19-44). Baseline DNA data were available for 135 of the 150 (90%) women. There were no high-grade cervical lesions or cervical cancer on cytology or biopsy at baseline. The proportion of women at baseline who were naïve (seronegative and DNA-negative) to HPV 6, 11, 16 and 18 and the percentage that seroconverted at week 28 and 52 are shown in the table. There were no vaccine-related serious adverse events. There were no significant differences among the 3 enrollment groups in terms of the proportion seroconverting. Titers to HPV 6, 11 and 18 did not differ between groups, but did significantly differ for HPV 11 with Group 3 having higher median titers (3035) than Group 1 (2262) or Group 2 (1975) (p=0.025).

Conclusions: The qHPV vaccine was safe and immunogenic in Indian HIV-infected women, regardless of CD4 level and HIV viral load. A high proportion of Indian HIV-infected women were “naïve” to vaccine HPV types. These women should be considered for HPV vaccination to reduce their risk of cervical cancer even though their mean age exceeded 26 years, the upper limit for catch-up vaccination in many countries.

| Prior exposure to HPV vaccine types at baseline and seroconversion at week 28 and 52 |
|---------------------------------|----------|----------|----------|----------|
| HPV 6  | HPV 11 | HPV 16 | HPV 18  |
| Percent naive (seronegative and HPV DNA-negative) at baseline | 71% | 87% | 73% | 81% |
| Percent seronegative at baseline who seroconverted at week 28 | 100% | 99% | 99% | 88% |
| Week 28 seroconverters remaining seropositive at week 52 | 96% | 97% | 99% | 78% |

856 B and T Cell Immune Responses To pH1N1 Monovalent Vaccine in HIV+ Pregnant Women in IMPAACT P1086

Adriana Weinberg1, Petronella Muresan2, Kelly Richardson3, Terrence Fenton3, Teresa Dominguez3, Anthony Bloom4, Mark Abzug5, Myron Levin1, Sharon Nachman5
1Pediatric Infectious Diseases, University of Colorado Denver, Aurora, CO, United States, 2Harvard School of Public Health, Boston, MA, United States, 3Frontier Science & Technology Research Foundation, Amherst, NY, United States, 4The Children’s Hospital, Aurora, CO, United States, 5State University of New York at Stony Brook, Stony Brook, NY, United States

Background: Pregnant women have a high risk of severe influenza disease that can be mitigated by vaccination. Although HIV+ individuals have modest antibody responses to influenza vaccines, vaccination has been effective against disease, suggesting additional mechanisms of protection. We characterize the B and the T cell responses to pH1N1 vaccine and their determinants in HIV+ pregnant women.

Methodology: 57 HIV+ pregnant women received two 30 μg doses of pH1N1 vaccine and had the following studies at entry and post-dose 1 and 2: IgG & IgA B cell ELISPOT; interferon (IFN)γ & granzyme B (GrB) T cell ELISPOT; hemagglutination inhibition (HAI) antibody titers; and B and T cell subsets by flow cytometry.
Results: Participants had mean± S.D. age = 27± 5 years, CD4 = 521± 223 cells/μL and plasma log 10 HIV RNA = 2.3± 0.9 copies/mL. All women were on antiretroviral treatment, including 51 on HAART.

HAI titers increased from median (interquartile range) of 20 (5, 40) at entry to 160 (40, 320) post-dose 1 and 2 (p=0.0001). ELISPOT-measured IgG antibody-secreting cells (ASC) increased from 6 (2, 28)/10^6 mononuclear cells (MNC) to 15 (4, 6) post-dose 1 (p=0.01) and 14 (6, 70) post-dose 2 (p=0.003). IgA ASC were low at entry [1 (0, 9)] and did not change after vaccination. ELISPOT-measured IFNγ spot-forming cells (SFC) decreased from 166 (38, 324)/ 10^6 MNC to 117 (40, 506) post-dose 1 and 76 (32, 336) post-dose 2 (p=0.06 post-dose 1 vs. 2). Vaccination did not change GrB SFC [entry of 48 (12, 258)].

IFNγ and GrB SFC inversely correlated with plasma HIV RNA at all time points (ρ ≤ -0.35, p ≤ 0.02) and IFNγ SFC positively correlated only with CD4% at entry (p = 0.31, p = 0.04). There were no significant correlations of ASC or HAI titers with HIV disease characteristics.

At all time points, IFNγ and GrB SFC were highly correlated with each other (ρ ≥ 0.67, p< 0.0001). IFNγ SFC correlated with HAI titers at all time points (ρ ≥ 0.29; p ≤ 0.06). IgG ASC did not correlate with IFNγ or GrB SFC or HAI titers.

The table shows correlations of pH1N1 immune responses with the frequency of B and T cell subsets.

Conclusions: HIV+ pregnant women developed pH1N1 IgG, but not IgA, B cell immunologic memory after vaccination. pH1N1 T cell immunity was present at entry, did not increase after vaccination, and IFNγ SFC decreased post-dose 2. High Treg, Breg and activated T cells were associated with low T cell immunity, but high IL10+ Treg and Breg and activated B cells were associated with high B cell memory. High FOXP3+ Treg were associated with low B and T cell immunity.
Conclusions: Maternal CD4 immune deficiency was specifically and significantly associated to an increased risk of serious bacterial infections in HEU infants during the first year of life, especially beyond the neonatal period. This reinforces the need to explore the effects of in-utero exposure to maternal HIV on the infant immune system.

Fig 1. Serious bacterial/viral infection-free survival during first year of life according to maternal CD4 cell count (N=7638 infants)

858 Effect of Breastfeeding On Mortality and Morbidity in HIV-Exposed Un-Infected Children in Uganda
Carina Marquez, Jaffer Okiring, Gabriel Chamie, Jane Achan, Theodore Ruel, Abel Kakuru, Moses R. Kamya, Edwin D. Charlebois, Grant Dorsey, Diane V. Havlir

1University of California, San Francisco, San Francisco, CA, United States; 2Infectious Diseases Research Collaboration, Kampala, Uganda; 3Makerere University College of Health Sciences, Kampala, Uganda

Background: There is a growing population of HIV-exposed un-infected children (HEU), a population with a high risk of mortality. Prior studies examining the association of HIV-exposure and mortality and infectious morbidity have either lacked a comparison to HIV-unexposed un-infected children (HUU) or did not assess the effect of breastfeeding. We leveraged data from a cohort in rural Uganda to assess whether this association persists when controlling for breastfeeding and poverty.

Methodology: We included longitudinal data from 186 HEU (544 person-years) and 389 HUU (264 person-years) children ages 6-24 months enrolled in the PROMOTE cohort and participating in a trial on the effect of antimalarial chemoprevention. Children received medical care at the study clinic per standardized protocols. Outcomes assessed were: all-cause mortality, hospitalization, severe febrile illness (SFI, composite of severe pneumonia or sepsis syndrome), severe diarrhea, malnutrition, and malaria. Generalized estimating equation regression models were used to assess risk, and all models were adjusted for age, breastfeeding, SES, and malaria chemoprevention (trimethoprim sulfamethoxazole, dihydroartemisinin-piperaquine, or sulfadoxine-pyrimethamine). To examine the interaction between HIV-exposure, age, and breastfeeding a sub-analysis was performed for the 6-12 month age strata with three risk categories: HUU non-breastfeeding, HEU breastfeeding, and HEU not-breastfeeding. HUU non-breastfeeding children were excluded from this sub-analysis due to lack of person-time.

Results: There were 7 (1.6%) deaths among HEU and 1 (0.3%) death among HUU. HEU compared to HUU had a higher relative risk of death (RR 13.5, p=0.04). The risk of malnutrition was lower in HEU compared to HUU (RR 0.6, p<0.001). The association of HIV-exposure and hospitalization, SFI, severe malnutrition, and severe diarrhea were not significant for children 6-24 months. However, when we assessed the combination of HIV-exposure and breastfeeding status in the 6-12 month age strata we found a significantly higher risk of morbidity outcomes compared to the reference group of breastfeeding HUU children were at a significantly high risk of morbidity outcomes compared to the reference group of breastfeeding HUU: hospitalization (RR: 10.3, p<0.001), SFI (RR: 3.8, p<0.001), severe diarrhea (RR: 6.5, p<0.001), and malnutrition (RR: 18.7, p<0.001). Antimalarial chemoprevention did not have a significant effect on health outcomes other than malaria.

Conclusions: HEU had higher risk of mortality compared to HUU, and breastfeeding is a key mediator of the association of HIV-exposure and non-malaria morbidity for children in this cohort.

859 Growth Differences in Infants Born To Perinatally vs. Non-Perinatally HIV-Infected Women
Jennifer Jao, Allison Agwu, Grace Mhango, Annie Kim, Kaye Park, Roberto Posada, Elaine J. Abrams, Nancy Hutton, Rhoda S. Sperling

1Medicine, Obstetrics Gynecology & Reproductive Science, Icahn School of Medicine at Mount Sinai, New York, NY, United States; 2Pediatrics, Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States; 3Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, United States; 4Pediatrics, Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States; 5Obstetrics, Gynecology & Reproductive Science, Icahn School of Medicine at Mount Sinai, New York, NY, United States; 6Obstetrics, Gynecology & Reproductive Science, Icahn School of Medicine at Mount Sinai, New York, NY, United States; 7ICAP-Columbia University, Mailman School of Public Health, New York, NY, United States; 8Obstetrics, Gynecology & Reproductive Science, Icahn School of Medicine at Mount Sinai, New York, NY, United States

Background: Pregnancy & infant growth outcomes are not well documented in perinatally HIV+ (PHIV) women & their children. We evaluate growth to 1 year in infants of PHIV vs. non-perinatally HIV+ (NPHIV) women.

Methodology: Using routinely collected weight, length, & head circumference data, we evaluated weight-for-age (WAZ), length-for-age (LAZ), weight-for-length (WFLZ), & head circumference-for-age (HCAZ) z scores from birth to 1 year in HIV-exposed uninfected (HEU) infants born to PHIV vs. NPHIV women. HIV+ pregnant women & their infants received care at one of two urban hospitals & delivered from January 2004-March 2012. Twin pregnancies,
those ending in termination or fetal demise, infants ≤28 weeks gestational age (GA), & HIV+ infants were excluded. Demographic, clinical, & antiretroviral therapy (ART) history were collected via chart review. Linear mixed effects models were used to evaluate the effect of PHIV on WAZ, LAZ, & WFLZ.

Results: Of 152 infants, 32 were born to 25 PHIV women. PHIV women were younger (20 vs. 26 years, \( p<0.001 \)) had lower gravidity (1 vs. 3, \( p<0.001 \)), lower pre-pregnancy BMI (24.1 vs. 27.9 kg/m², \( p=0.039 \)), & height (155 vs. 160 cm, \( p=0.009 \)) than NPHIV women. PHIV women were also more likely to harbor lower nadir CD4+ cells in pregnancy (20 vs. 2% with <50 cells/mm³, 16 vs. 11% with 50-200 cells/mm³, \( p=0.004 \)) & receive second line ART (24 vs. 4%, \( p=0.005 \)). They were less likely to attain HIV RNA levels <400 copies/ml by delivery than their NPHIV counterparts (68 vs. 87%, \( p=0.036 \)). Infant GA, race, & APGARS did not differ between groups. Median birth WAZ was lower in infants born to PHIV women (-1.61 vs. -0.81, \( p=0.032 \)); birth LAZ, WFLZ, & HCAZ did not differ significantly between groups. Infants born to PHIV women exhibited lower WAZ & LAZ through 1 year. In multivariate analysis, the relationship between PHIV & LAZ persisted (\( \beta=-0.54, \ p=0.026 \)). Small-for-gestational age (SGA) for birth length (BL) was associated with decreased LAZ (\( \beta=-0.48, \ p=0.007 \)), for birth weight (BW) with decreased WAZ (\( \beta=-0.99, \ p<0.001 \)) & for BW/BL with decreased WLZ (\( \beta=-0.36, \ p=0.027 \)). A delivery HIV RNA level <400 copies/mL was associated with increased WAZ & WLZ (\( \beta=0.43, \ p=0.015 \); \( \beta=0.38, \ p=0.021 \)).

Conclusions: HEU infants born to PHIV women may be at risk for decreased length in the first year of life, while maternal viral suppression may be protective for growth. HEU infants born to these women may require close observation & long term follow up of growth.

Figure. Less Plots of Mean Weight for Age (WAZ) and Length for Age (LAZ) Z scores by Maternal HIV Acquisation

860LB Four Year Cotrimoxazole Prophylaxis Prevents Malaria in HIV-Exposed Children: A Randomized Trial

Jaco Homsy1, Grant Dorsey1, Emmanuel Arinaitwe1, Humphrey Wanzira1, Abel Akuru1, Victor Bigira1, Mary Muhindo2, Moses R. Kamya1, Taylor G. Sandison1, Jordan W. Tapper1

1Global Health Sciences, University of California San Francisco, San Francisco, CA, United States; 2School of Medicine, University of California San Francisco, San Francisco, CA, United States; 3Infectious Diseases Research Collaboration, Kampala, Uganda; 4Medicine, Makerere University School of Medicine, Kampala, Uganda; 5Medicine, University of Washington, Seattle, WA, United States; 6Centers for Disease Control and Prevention, Atlanta, GA, United States

Background: WHO recommends cotrimoxazole (CTX) prophylaxis for children born to HIV-infected mothers from 6 weeks of age until breastfeeding cessation and exclusion of HIV infection. We report on the protective efficacy and safety of CTX prophylaxis in these children when continued beyond breastfeeding cessation to age 4.

Methodology: We conducted an open-label randomized controlled trial alongside two observational cohorts in Eastern Uganda, an area of high HIV prevalence, malaria transmission intensity, and antifolate-resistance. 203 HIV-exposed infants enrolled between 6 weeks and 9 months of age were prescribed daily CTX until breastfeeding cessation and HIV status confirmation. After breastfeeding ended, 185 children remained in active follow-up and HIV-uninfected and were randomized 1:1 to discontinue or continue CTX prophylaxis until age 2 years. At that age, the 91 children who continued CTX were randomized 1:1 again to continue or discontinue CTX from age 2 through age 4. For additional comparisons, 48 HIV-infected children on continuous CTX prophylaxis and 100 HIV-unexposed uninfected children who never received CTX prophylaxis were enrolled. All children were followed to age 5. Main outcome measures included malaria incidence, grade 3 and 4 serious adverse events (SAEs), and hospitalizations.

Results: Out of the 185 HIV-exposed children who remained enrolled and HIV-uninfected after the end of breastfeeding, 152 (82.2%) and 146 (78.9%) randomized HIV-exposed children were followed to age 4 and 5 respectively. Continuing CTX prophylaxis to age 4 yielded a 43% reduction in malaria (incidence rate ratio, 0.57; 95% CI, 0.49-0.66; p<0.001). Throughout follow-up, malaria incidence was lowest among HIV-infected children who received continuous CTX prophylaxis and highest among HIV-negative unexposed children who never received CTX prophylaxis. There were no significant differences in incidence of grade 3 or 4 SAEs, hospitalizations, or deaths among HIV-exposed, HIV-unexposed, and HIV-infected children. There was no evidence of malaria incidence rebound in the year following discontinuation of CTX at age 2 or 4, but incidence increased significantly from age 4 to 5 among children who stopped CTX at age 4.

Conclusions: These results indicate that continuing cotrimoxazole prophylaxis beyond the period recommended by WHO is safe and efficacious in protecting HIV-exposed children living in malaria endemic areas even in the presence of high anti-folate resistance.

861 No Evidence of Neurodevelopmental Delay in HEU Infants Exposed to cART In Utero and Breastfeeding

Mary Ngoma1, Jessica Harper2, Jennifer Hunter2, Paige Church3, Helene Cote3, Chisomo Selemani1, Mulla Chandwe1, Arianne Albert3, Marylou Smith2, Michael Silverman2

1University of Zambia, Lusaka, Zambia; 2University of Toronto, Ajax, ON, Canada; 3University of British Columbia, Vancouver, BC, Canada

Background: The 2013 WHO Guidelines on preventing mother-to-child transmission (PMTCT) of HIV recommend maternal cART throughout pregnancy and for 1 year of breastfeeding for HIV infected mothers in many developing countries. Some antiretrovirals (in particular zidovudine and 3TC) are well secreted in breast milk. The neurocognitive impact of prolonged cART exposure on the developing brain of the HIV-exposed uninfected (HEU) infant is currently unknown.

Methodology: Between June 2011 and August 2013, children aged 15-36 months were recruited to a cohort study from the Chelstone Clinic in Lusaka, Zambia. Group A (exposed) children were born to HIV+ women who received ZDV300mg/3TC150mg and Lopinavir400mg/ritonavir100mg all BID starting between 14-30 weeks gestation and through 1 year of breastfeeding postpartum. Group B (control) HIV non-exposed children were recruited from the Chelstone under-5 health clinic. The standardized Capute Scales assessment tool, which consists of the Cognitive Adaptive Test and Clinical Linguistic and Auditory Milestone Scale, was used to assess nonverbal problem-solving and language skills. A score <85 on the Capute Full Scale Developmental Quotient (FSDQ) was considered indicative of developmental delay and the primary outcome compared between the two groups. Additionally, the assessment included a demographic questionnaire, anthropometric measurements, and biological samples to confirm HIV status of the child and mother. HIV positive infants were excluded from enrollment.

Results: Two hundred children completed the neurocognitive assessments (Group A, n=97; Group B, n=103). There were no significant differences in maternal age, gestational age at birth or duration of breastfeeding, between groups. An FSDQ score <85 was found in 8 (8.3%) of Group A participants and 15 (14.6%) of Group B participants. In univariate logistic regressions, lower income (OR=0.93, 95%CI=0.84-0.99, p=0.02), older infant age (OR=1.08, 95%CI=1.01-1.17, p=0.03), and lower birth weight (OR=0.16, 95%CI=0.05-0.44, p=0.0002) were associated with the probability of FSDQ <85, while group (A vs. B) was not (OR=1.88, 95%CI=0.77-4.87, p=0.16). In the multivariable analysis, only lower birth weight (OR=0.17, 95%CI=0.05-0.50, p<0.001) and older age (OR=1.10, 95%CI=1.01-1.21, p=0.03) remained associated with FSDQ <85.

Conclusions: There was no evidence of a higher proportion of delayed infants in the HEU group when compared to a similar HIV unexposed control group. These results suggest that this cART regimen during pregnancy and prolonged breastfeeding does not impact early childhood cognitive development. This finding is reassuring in light of the recent substantial increase in perinatal and postpartum use of cART worldwide.

### 862 In Utero Exposure To Zidovudine and Neonatal Heart Abnormalities in the ANRS-EPF/PRIMEVA Studies

**Jeanne SibUDGE-1,2, Jérôme Le Chenade3, Damien Bonnet4, Roland Tubiana4,5, Laurent Mandelbrot4,1, Sandrine Delmas3, Camille Runel Bellard4, Babak Khoshnood5, Josiane Warszawski2,7, Stéphane Blanchet2,13, for the ANRS-French Perinatal Cohort/PRIMEVA**

1 Obstetrics and Gynecology, AP-HP, Hôpital Louis Mourier, Colombes, France; 2CESP, INSERM U1018, Le Kremlin-Bicêtre, France; 3Paediatric Cardiology M3C, AP-HP Hôpital Necker, Paris, France; 4Univ Descartes Paris 5, Paris, France; 5Infectiology, AP-HP Hôpital Pitié Salpêtrière, Paris, France; 6INSERM U943, Paris, France; 7Univ Diderot Paris 7, Paris, France; 8Pédiatric, Centre Hospitalier Pellegrin, Bordeaux, France; 9Ceped, UMR 5823, Université Paris 6, Paris, France; 10CESP, INSERM U1016, Univ Paris Sud, Le Kremlin-Bicêtre, France; 11AP-HP Hôpital Necker, Paris, France; 12Pédiatrics, AP-HP Hôpital Necker, Paris, France; 13EA 3620, Univ Descartes Paris 5, Paris, France

**Background:** Antiretroviral therapy (ART) effectively prevents mother-child transmission of HIV. An increased risk of congenital heart defects (CHD) has been reported in infants exposed in utero to zidovudine, the association being strong and specific in a recent large EPF study. Observational studies have also found modification in myocardial mass and contractility in infants, particularly girls, similar to the effects of anthracyclin cardiac toxicity.

We reevaluated these associations with the national ANRS EPF cohort and nested Primeva randomized trial.

**Methodology:** The EPF-C01/C011 has, since 1986, prospectively enrolled nearly 20,000 mother-child pairs from HIV-infected women delivering in 90 centers throughout France. The relationships between ART and each kind of congenital defect, as routinely collected, have already been studied among 13,124 livebirths between 1994 and 2010. Here, all CHD were reviewed, sites contacted for additional information, and adjudicated by a CHD specialist, blind to in utero exposure.

The phase II/III ANRS-135 PRIMEVA trial was run between 2007 and 2012 in the EPF sites to evaluate a nucleoside-sparing strategy. Women were randomized to receive either LPV/r alone (n=69) or AZT+3TC+LPV/r (n=36) in the last trimester of pregnancy. Infant echocardiogram was planned at 1 and 12 months of age. At least one echocardiogram was performed in 50 infants.

**Results:** In EPF, zidovudine (vs no zidovudine) in the first gestational trimester was significantly associated with congenital heart defects, before and after adjustment for potential confounding variables and concomitant antiretroviral medication: 1.5% vs. 0.7%, p < 0.001; Adjusted Odds Ratio = 2.2 [95% CI 1.3-3.7]. This association mainly involved ventricular septal defects: 1.1% vs. 0.6%, p = 0.001, but not atrial septal defects, both classified as minor CHD. The association was also significant for major CHD: 0.31% vs. 0.11%, p = 0.02, but the numbers of cases was small.

In Primeva, AZT+3TC+LPV/r (versus LPV/r alone) in the last gestational trimester was associated - in girls only - with higher median left ventricle fractional shortening at 1 month (40% vs. 36%; p = 0.008), and with median posterior wall thickness at 1 year (5.4 vs. 4.4 mm, p = 0.01). No differences were observed among boys.

**Conclusions:** Our results from a large cohort and a randomized trial indicate that zidovudine may affect heart development and/or cardiac function, although its clinical impact is unknown. Potential mechanisms underlying these associations, maybe involving mitochondrial dysfunction, must be investigated. This should be taken into consideration when monitoring the long-term health of children born to HIV+ mothers, given the large number of children exposed to perinatal zidovudine worldwide.

---

### 863LB Congenital Anomalies and In Utero Antiretroviral Exposure in HIV-Exposed Uninfected Children

**Paige L. Williams1, Cenk Yildirim2, Marilyn Cahn1, Rohan Hazra3, Russell B. VanDyke4, Kenneth Rich5, Jennifer S. Read6, Emma Stuard7, Mobeen Rathore9, D. Heather Watts10, for the Pediatric HIV/AIDS Cohort Study**

1Departments of Biostatistics and Epidemiology, Harvard School of Public Health, Boston, MA, United States; 2Center for Biostatistics in AIDS Research, Harvard School of Public Health, Boston, MA, United States; 3Department of Pediatric Infectious Diseases, University of Alabama at Birmingham, Birmingham, AL, United States; 4Maternal and Pediatric Infectious Disease Branch, National Institute of Child Health and Human Development, Bethesda, MD, United States; 5Department of Pediatrics, Tulane University School of Medicine, New Orleans, LA, United States; 6Department of Pediatrics, University of Illinois at Chicago, Chicago, IL, United States; 7Department of Pediatrics, George Washington University School of Medicine, Washington, DC, United States; 8Department of Pediatric Infectious Disease, Bronx-Lebanon Hospital, Bronx, NY, United States; 9University of Florida at Jacksonville, Jacksonville, FL, United States; 10Office of the U.S. Global AIDS Coordinator, U.S. Department of State, Washington, DC, United States

**Background:** Most studies examining the association of maternal antiretroviral (ARV) exposures during pregnancy with congenital anomalies (CAs) in their children have been reassuring, but some suggest increased risk with specific ARVs.

**Methodology:** We evaluated HIV-exposed uninfected children enrolled in the PHACS Surveillance Monitoring of ART Toxicities (SMARTT) study, an ongoing prospective cohort study initiated in 2007 at 22 sites in the US including Puerto Rico. Information on CAs was collected by chart abstraction or from prior models were used to evaluate associations between CAs and 1st trimester exposure to any ARV, specific ARVs, combination ARV regimens (≥3 drugs from ≥2 classes), and ARV classes. Models were adjusted for demographic and maternal characteristics (including CD4, viral load, substance use, other medications, and pregnancy complications).

**Results:** Among 2580 children born by July 2012 (49% female, 66% black, 33% Hispanic), 162 had a total of 242 confirmed major CAs, and 13 had ≥2 conditional CAs, for a total of 175 cases (6.78%, 95% CI: 5.85-7.82%). The most common anomalies were musculoskeletal (n=72) and cardiovascular (n=56). The prevalence of CAs by birth cohort was 3.8%, 5.2%, 8.0%, 8.3%, and 5.7% for children born ≥2001, 2002-2004, 2005-2007, 2008-2010, and ≥2011, respectively. In unadjusted models, 1st trimester exposures to combination ARV regimens or to protease inhibitors (PIs) were associated with increased risks of CAs (odds ratio (OR)=1.44, p=0.022 and OR=1.51, p=0.010, respectively), but these associations did not persist after adjustment. No individual NNRTI (including efavirenz) or NRTI was associated with an increased risk of CAs, but the combination of ddI+d4T (<1% exposed) was...
associated with 8-fold higher odds [adjusted OR (aOR)=8.41, p=0.015]. Among individual PIs, atazanavir and lopinavir were associated with significantly higher odds of CAs in unadjusted models, and the association with atazanavir persisted in adjusted models (aOR=1.93, p=0.004). With 1st trimester atazanavir, risks were highest for skin CAs (aOR=5.24, p=0.020) and musculoskeletal CAs (aOR=2.55, p=0.007).

Conclusions: Few individual ARVs or drug classes were associated with increased risk of CAs after adjustment for child and maternal characteristics, with the exception of the combination of ddI+d4T, now rarely used, and atazanavir, which is increasing in use. As newer ARVs and ARV combinations become more widely used, continued monitoring is essential.

### 865 Abnormal Fatty-Acid Oxidation in HIV-Exposed Uninfected neonates in the United States

Brian Kirmse1, Izy-Jyun Yao1, Sean Holthen1, Paige Williams1, Deborah Kacanek2, Rohan Hazra1, William Borkowski1, Russell Van Dyke1, Marshall Summar1

1Genetics & Metabolism, Children’s National Medical Center, Washington, DC, United States; 2Harvard School of Public Health, Boston, MA, United States; 3National Institutes of Health, Bethesda, MD, United States; 4Pediatrics, New York University School of Medicine, New York, NY, United States; 5Tulane University School of Medicine, New Orleans, LA, United States

Background: Abnormal newborn screens for dysfunctional fatty acid oxidation (FAO) are more common in HIV-exposed uninfected (HEU) neonates than the general population and may be related to in utero exposure to HIV and/or combination antiretroviral therapy (cART). Normal FAO is necessary for normal growth and development. Disordered FAO can result in hypoglycemia, myopathy and liver injury.

Methodology: We analyzed serum acylcarnitine profiles (ACP), as a measure of FAO, in 522 HEU neonates (age 0–7 days) enrolled in the SMARTT study of the Pediatric HIV/AIDS Cohort Study (PHACS). We estimated the prevalence of abnormal ACP and evaluated associations of abnormal ACP with in utero exposure to cART and antiretroviral (ARV) drug classes in logistic regression models, adjusting for maternal demographic characteristics and substance use. We also evaluated associations of abnormal ACP with clinical laboratory parameters (lactate, glucose, creatine kinase (CK) and alanine aminotransferase (ALT)) and measures of neurodevelopment and growth through 3 years of age.

Results: Of 522 neonates, 84 (17%) had abnormal ACP, with most abnormal profiles characterized by generalized or long-chain specific acylcarnitine elevations. Maternal alcohol exposure (adjusted odds ratio (aOR)=2.55, 95% confidence interval (CI): 1.21, 5.37, p=0.01) and, as expected, lower gestational age at birth (aOR=1.21 per week lower, 95% CI: 1.07, 1.36, p<0.01) were associated with higher odds of having an abnormal ACP. In analyses adjusted for alcohol exposure and gestational age, in utero exposure to a protease inhibitor (PI) was associated with higher odds of having an abnormal ACP (aOR=1.79, 95% CI: 1.06, 2.99, p=0.03) while exposure to a non-nucleoside reverse transcriptase inhibitor (NNRTI) (aOR=0.23, 95% CI: 0.07, 0.80, p=0.02) was associated with lower odds of having abnormal ACP. ALT levels were higher in those with abnormal vs. normal ACP (geometric mean 18.7 U/L vs. 14.9 U/L, p<0.01), but no differences in lactate, glucose or CK were observed. ACP status was not associated with MacArthur-Bates Index and Bayley Score at 1 year or anthropometric measurements at 2 and 3 years of age.

Conclusions: Abnormal ACP, indicating dysfunctional FAO, are relatively common in HEU neonates and are associated with PI use and maternal alcohol exposure during pregnancy as well as higher neonatal ALT levels. Taken together, these observations suggest the possibility of subclinical hepatic dysfunction in HEU newborns. Abnormal ACP is not associated with levels of CK, glucose, lactate or significant delays in growth or development. Further studies are needed to determine the long-term clinical implications of abnormal FAO in HEU neonates.

### 866 Comparative Genotoxic Signatures in Cord Blood Cells From Neonates Exposed To AZT or TDF In Utero

Background: Zidovudine (AZT) and tenofovir (TDF) are the most frequently used nucleoside analogues for reducing perinatal HIV transmission during pregnancy. Various genotoxicity biomarkers have been identified in neonates and animal models exposed to AZT in utero. In contrast, there are no data on TDF exposure - even though the compound is now considered by the WHO as a benchmark drug in this setting. We have previously shown that cord blood cells from neonates exposed to AZT in utero present a higher proportion of aneuploid cells and have a transcriptome profile that is suggestive of increased DNA alteration and repair. The aim of the present study was to compare the genotoxic signatures in neonates exposed to either AZT or TDF in utero.

Methodology: Cord blood cells from neonates exposed to either AZT or TDF in utero were used to enrich CD34+ hematopoietic stem/progenitor cells (HSPCs) or CD3+ T lymphocytes. The cells were then subjected to blinded karyotyping and a transcriptome analysis.

Figure. Aneuploidy Rates in Cord Blood Cells of In Utero Exposed Newborns to AZT or TDF Based Antiretroviral Combinations or Controls

The aneuploidy rates were determined as the percentage of all scored cells that were aneuploid for each antiretroviral-exposed and control samples. Bars represent means. * : p < .05.
Results: Karyotyping revealed a higher proportion of aneuploid cells in the AZT-exposed group (n=7, mean ± SD: 26.3% ± 9.2) than in the TDF-exposed group (n=8, 14.2% ± 6.7; p<0.05) and a control group (n=6, 13.3% ± 7.2; p<0.05) (figure). All chromosomes were involved and the alterations were randomly distributed. Our overall analysis of transcriptome profiles revealed a distinct molecular profile in patients exposed to AZT or TDF. This signature was found both in CD34+ HSPCs and CD3+ T lymphocytes. Gene Set Enrichment Analysis revealed significant changes in the activity of genes involved in DNA repair in both the AZT and TDF groups. However, in HSPC experiments, double-strand break repair, Fanconi anaemia pathway and G2/M checkpoint gene sets were enriched in the AZT group but not in the TDF group.

Conclusions: Based on our cytogenetic analysis, antiretroviral (ARV) combination treatments that include TDF may be less clastogenic than those including AZT. However, hematopoietic cord blood cells present transcriptional abnormalities that are suggestive of DNA damage in neonates exposed to AZT- or TDF-based ARV combination treatments in utero. Given the wide use of these ARV drugs during pregnancy, it is critical to further investigate their genotoxicity and potential impact on health.

867 Risk Factors for Preterm Birth in Pregnant Women Randomized To Lopinavir- or Efavirenz-Based ART
Catherine A. Koss1, Paul Natureeba2, Albert Plenty3, Flavia Luwedde1, Julia Mwesigwa1, Edwin Charlebois4, Tamara Clark2, Bridget Nzurubara2, Moses Kamya4, Diane Havir5, Deborah Cohran3
1Division of HIV/AIDS, University of California San Francisco, San Francisco, CA, United States, 2Infectious Diseases Research Collaboration, Kampala, Uganda, 3Center for AIDS Prevention Studies, University of California San Francisco, San Francisco, CA, United States, 4Makerere University College of Health Sciences, Kampala, Uganda, 5Department of Obstetrics, Gynecology and Reproductive Sciences, University of California San Francisco, San Francisco, CA, United States

Background: Preterm birth (PTB) is a major cause of perinatal morbidity and mortality. HIV-infected pregnant women, particularly those with advanced disease, may have higher rates of PTB than HIV-uninfected women. As countries adopt WHO Option B+ and more women start combination antiretroviral therapy (cART), it is critical to understand risk factors for PTB among HIV-infected pregnant women on cART.

Methodology: This is a planned secondary analysis of PTB in the PROMOTE-Pregnant Women and Infants Study (NCT00993031). This was an open-label, randomized controlled trial comparing the risk of placental malaria among HIV-infected, ART-naive pregnant Ugandan women at 12-28 weeks gestation who were randomized at study enrollment to receive lopinavir/ritonavir (LPV/r) - or efavirenz (EFV)-based cART. All women received daily trimethoprim-sulfamethoxazole and bednets. All eligible, randomized women were included in this analysis with censoring at time of study withdrawal or live birth after 37 weeks gestation. Gestational age at enrollment was calculated by last menstrual period and ultrasound biometry. PTB was defined as less than 37 weeks and very PTB as less than 32 weeks gestation. We excluded stillbirths and spontaneous abortions. Placental malaria was examined by blood smear, rapid diagnostic test, and PCR. Multivariate Cox proportional-hazards modeling was used to evaluate risk factors for PTB.

Results: A total of 389 eligible women were enrolled; mean gestational age was 20.8 weeks and median CD4 cell count was 369 cells per microliter (IQR 272–493). Among 356 live-born singleton deliveries, the prevalence of PTB was 15.4% and the prevalence of very PTB was 1.7%. Univariate risk factors for PTB were gestational age at study enrollment (and hence cART start) of 24-28 weeks vs. 12-23 weeks (HR = 1.85, 95% CI: 1.09-3.14, p = 0.03) and study period weight gain of less than 0.1 kg/week vs. 0.1 kg/week or more (HR = 2.32, 95% CI: 1.37-3.94, p = 0.002). Placental malaria was not a risk factor for PTB (HR = 0.95, 95% CI: 0.34-2.66, p = 0.93), nor was antiretroviral regimen of LPV/r vs. EFV (HR = 1.10, 95% CI: 0.65-1.88, p = 0.70). In multivariate analysis controlling for time since HIV diagnosis, gestational age at cART start greater than 24 weeks was significantly associated with PTB (aHR = 1.80, 95% CI: 1.06-3.07, p = 0.03), whereas antiretroviral regimen was not (aHR = 1.15, 95% CI: 0.60-1.97, p = 0.60).

Conclusions: In this cohort of HIV-infected pregnant women presenting at 12-28 weeks gestation, starting cART at an earlier gestational age was associated with a reduced risk of preterm birth. There was no difference in the risk of preterm birth among women randomized to LPV/r- or EFV-based cART.

Pregnancy Incidence and Outcomes Among Women in ART Programs
868 Incidence and Predicting Factors of Pregnancy Post-ART Initiation in 9 West African Countries
Juan Burgos-Soto1,2, Eric Balestre1, Albert Minga1, Samuel Aiyaj1, Adrien Sawadogo1, Marcel D. Zannou1, Valérie Leroy1,2, Didier K. Ekouevi2,7, François Dabis1,2, Renaud Becquet1, LeDEA West Africa Collaboration

Background: In sub-Saharan Africa, women of reproductive age constitute the most HIV-affected population. Since antiretroviral therapy (ART) has become widely available, HIV-infected women health status has improved and the pregnancy rate post-ART has risen. In order to correctly respond to reproductive health needs of HIV-infected women in reproductive age, estimating incidence and predicting factors of pregnancy after ART initiation is crucial. This study estimated these outcomes among HIV-infected women after ART initiation at 15 clinical sites in nine West-African countries over a 10-year period.

Methodology: This retrospective cohort analysis was conducted within the International epidemiologic Databases to Evaluate AIDS (LeDEA) West Africa collaboration. All HIV-infected women aged <50 years, starting ART for their own health according to country-specific protocols between 2002-2011, and not reported pregnant at ART initiation were eligible for analysis. Ever becoming pregnant as reported in the database after ART initiation was the main outcome. Poisson regression analysis accounting for countries heterogeneity was used to estimate pregnancy incidence post-ART and to identify its
predicting factors. Incidence rate ratios were adjusted on baseline CD4 count; age, Body Mass Index & hemoglobin at ART initiation; first ART regimen; calendar year of ART start; time following ART initiation and country.

Results: Overall 27,489 HIV-infected women contributed for 75,403 women-year of follow-up to this analysis. At baseline, median age was 33 years old [IQR: 28.5-38.8] and median CD4 cell count was 170 cells/μl [IQR: 84-266]. During follow-up, 2,337 pregnancies were reported after ART initiation: 1,961 women reported one pregnancy, 167 and 14 women reported two and three pregnancies, respectively. Median time to first pregnancy after ART initiation was 24.2 months [IQR: 11.9-42.6]. The crude incidence rate of pregnancy was 3.1 per 100 women/year [95%CI: 3.0-3.2]. Pregnancy incidence rate was highest among women aged 16-24 years (4.7 per 100 women/year; 95%CI: 4.2-5.2); adjusted incidence rate ratio was 14.4 (95%CI: 10.6-19.5) when compared to women aged 40-49 years. Incidence of first pregnancy was higher during the first year post-ART initiation (15.5 per 100 women/year; 95%CI: 14.1-16.9); adjusted incidence rate ratio was 27.7 (95%CI: 24.1-31.9) when compared to women in at least their fourth year on ART.

Conclusions: In the West-African region, although probably underestimated, the incidence rate of pregnancy post-ART initiation was high. Importantly, this incidence was higher during the first year following ART initiation. Family planning services should be delivered to all women initiating ART accordingly to their desire of procreation.

869 Pregnancy and Retention or Progression To AIDS/Death Post-ART in 9 West African Countries
Albert Minga1, Juan Burgos-Soto2,3, Eric Balestre1-3, Benson Okwara4, Moussa Y. Maiga5, Akouda Patassi6, Eugène Messou7, Christian Wesje8, François Dabis2,3, Renaud Becquart1, IeDEA West Africa Collaboration

1Centre Médical de Suivi de Donneurs de Sang (CMDS), Abidjan, Côte d’Ivoire, 2INSERM, Centre INSERM U897 “Épidémiologie et Biostatistique,” Bordeaux, France, 3Université Bordeaux Segalen, Institut de Santé Publique Épidémiologie Développement (ISPED), Bordeaux, France, 4University of Benin Teaching Hospital (UBTH), Abujia, Nigeria, 5Service de Gastroentérologie, CHU Gabriel TOURE, Bamako, Mali, 6Centre Hospitalier Universitaire Sylvanus Olympo, Lomé, Togo, 7Programme PAC-CI, CHU de Treichville, Abidjan, Abidjan, Côte d’Ivoire, 8Bandim Health Project, INDEPTH Network, Bissau, Guinea-Bissau

Background: We hypothesized that pregnancy after antiretroviral therapy (ART) initiation may impact health outcomes among HIV-infected women. The objectives of this west-African multi-country study were to assess whether pregnancy post-ART initiation had an effect on the risk of loss to follow-up (LTFU), AIDS progression or death and on CD4 cells gain.

Methodology: This retrospective cohort analysis was conducted within the IeDEA West Africa collaboration. All HIV-infected women aged <50 years, starting ART for their own health at 13 clinical sites in 9 West-African countries over a 10-year period were eligible. First, the effect of pregnancy (time dependent variable) on LTFU, progression to AIDS/death 48 months after ART initiation was estimated by adjusted Cox regression models. Second, the mean gain of CD4 cells in the first 24 months following ART initiation was estimated in multivariable linear mixed models accounting for countries heterogeneity and according to the occurrence or not of pregnancy.

Results: The first analysis accounted for 12,851 HIV-infected women not pregnant and/or with no AIDS diagnosis at ART initiation, of which 864 (6.7%) reported at least one pregnancy at M48 post-ART initiation. Among women with pregnancy and no pregnancy, 15.2% and 12.7% progressed to AIDS or death and 8.3% and 24.8% were LTFU at M48, respectively. After adjustment on CD4 count, age, Body Mass Index, hemoglobin and regimen at ART initiation; calendar year at ART start and country, pregnancy reduced the risk of AIDS or death (aHR=0.71; 95%CI: 0.55-0.92) and the risk of becoming LTFU at M48 (aHR=0.71; 95%CI: 0.55-0.92). Overall 20,408 HIV-infected women accounted for the CD4 analysis, of which 1,561 (6.2%) reported at least one pregnancy at M24 post-ART. The mean gain of CD4 cells between ART initiation and M24 was significantly higher among women who experienced a pregnancy in the first six months following ART initiation, compared to those with no pregnancy (Table 1).

Conclusions: In West-Africa, pregnancy during early post-ART initiation is a common event and reduces by roughly one third both the risk of AIDS disease progression or death and the risk of LTFU at 48 months after ART initiation. Moreover, pregnancy post-ART initiation had no deleterious impact on immune response. However, we suspect an underreported pregnancy rate and that a significant proportion of LTFU might be dead. More complex sensitivity analyses are underway to address these two issues.

* Linear mixed models adjusted for CD4 count at baseline; age, Body Mass Index (BMI) and hemoglobin at ART initiation; initial ART regimen; calendar year of starting ART and country.

** For the reference group: baseline CD4 count <50 cells/μl, 16-24 years old women treated with nevirapine, starting ART in 2011, with BMI = 18.5-25kg/m², baseline hemoglobin<7.5g/dl and followed-up in Ivory Coast.
870 Maternal HIV Envelope V3-Specific IgG Responses Are a Correlate of Risk of Perinatal Transmission

Sallie P. Permar1, Youyi Fong2, Genevieve Fouda1, Nathan A. Vandergrift3, Peter Gilbert4, Guido Ferrari5, Munir Alam6, Georgia D. Tomaras7, Thomas N. Denny8, Barton F. Haynes9, Women and Infant Transmission Study Group
1Human Vaccine Institute, Duke University Medical Center, Durham, NC, United States, 2Fred Hutchinson Cancer Research Center, Seattle, WA, United States

Background: More than 300,000 infants become vertically-infected with HIV-1 annually, despite the availability of effective antiretroviral prophylaxis regimens. Immunologic interventions, such as a maternal or infant vaccine, will likely be required to eliminate pediatric HIV-1. Immune correlates of risk of HIV-1 acquisition were identified in the moderately-successful RV144 HIV-1 vaccine trial, including the potentially-protective Envelope (Env) variable regions 1 and 2 (V1V2) IgG response. In this study, we aimed to define whether the potentially-protective responses identified in the RV144 vaccine trial or other Env-specific antibody responses would also predict the risk of mother to child HIV-1 transmission (MTCT).

Methodology: Utilizing the Women and Infants Transmission Study (WITS) cohort of U.S., nonbreastfeeding HIV-infected mothers, which began enrolling prior to the availability of antiretroviral prophylaxis, we selected untreated, HIV-transmitting mothers (n = 83; 52% perinatum, 13% in utero and 35% unknown transmission mode) and a clinically-matched group of nontransmitting mothers (n = 165) with plasma samples available between 25 weeks of gestation and 2 months postpartum. A pilot study revealed no significant differences in the Env-specific humoral responses during this peripartum period. We utilized a multivariable logistic regression model to determine whether plasma IgG and IgA Env binding responses (including V1V2 and V3 regions), neutralizing antibody score, avidity, and antibody-dependent cell cytotoxicity predicted the risk of MTCT.

Results: Application of a primary immune variable model adapted from that applied to the RV144 trial revealed that neither the maternal Env V1V2 IgG response nor the Env breadth IgA score correlated with the risk of MTCT. However, assessment of additional binding antibody responses revealed that IgG responses against Env V3 correlated with the risk of MTCT (OR: 0.76, p = 0.04, q = 0.15). On secondary analysis, neutralizing antibody responses against tier 1 clade B variants MN and SF162 significantly correlated with the risk of peripartum transmission (OR: 0.54, p = 0.005, q = 0.1 for both). Finally, avidity of the IgG response against gp140 directly interacted with IgG responses against gp41, gp120, and V3 to predict the risk of MTCT (p = 0.01, q = 0.17-0.19).

Conclusions: Maternal Env V3 IgG and neutralizing responses inversely correlated with transmission risk of MTCT, revealing distinctions between humoral immune correlates of risk of MTCT and vaccine-elicited humoral immune correlates of risk of sexual HIV-1 transmission identified in the RV144 trial.

871 Ontogeny of HIV-Targeted CD4+ T Cells During Exclusive and Non-Exclusive Breastfeeding

Elizabeth J. McFarland1, Tina Powell2, Weiming Zhang3, Carolyne Oyongo-Makumbi4, Kelsey Melander5, Prossy Naluwaya6, Samuel Okurut7, Michael A. Eller4, Mary Glenn Fowler1, 2, Edward N. Janoff8, 9

Jackson Foundation for the Advancement of Medical Science, Bethesda, MD, United States

Background: Mixed breastfeeding (BF) is associated with a higher risk of mother-to-child transmission than exclusive BF (EBF), however the mechanisms of increased risk are unclear. We determined whether feeding practices alter the expression of CD4+ T cell phenotypes with increased susceptibility to HIV.

Methodology: We prospectively evaluated 99 HIV-exposed, but uninfected, breastfeeding Ugandan infants at birth, 2, 6, 12, 18, 24, and 48 wks. T cells in fresh blood were characterized by flow cytometry for naïve, central (CM), effector (EM), and effector RA+ (EMRA) memory phenotypes by differential expression of CD45RA/CCR7, for markers of gut homing (β7), and for activation (HLA-DR+/CD38+) on CD4+ and CD8+ T cells and for HIV susceptibility by expression of surface coreceptor CCR5 on CD4+ cells. FMO tubes were used to define gating. Mothers were counseled to practice EBF but made a study-independent choice of feeding practice. EBF infants (n=49) were reported to have received only breast milk at all visits through 24 wk. Non-exclusively breastfed infants (NX, n=19) received non-breast milk liquids or solids, ±continued BF, at ≥2 visits between 2-24 wk. There was one HIV-infected infant who was excluded from the analysis. Values are expressed as medians; p values determined by paired t test for changes over time and Wilcoxon Rank-Sum test for comparisons between EBF and NX.

Results: In the whole cohort at birth, although most CD4+ T cells were naïve (91.7%), memory cells were already detected, particularly CM (6.9%). CM and EMRA T cells expressing CCR5 were present at birth and increased 2.6-fold from birth to 2 wk (3.0% vs. 7.9%, p<0.001). Memory CD4+ cells with gut-homing β7hi expression were rare at birth but increased progressively from birth to 48 weeks among CM (1.3% vs 14.4%, p=<0.001) and EM (1.6% vs 7.0%, p<0.001). We identified specific differences between EBF and non-exclusive BF (NX) by 24 weeks, when feeding practices had diverged. NX had a higher frequency of HIV-targeted β7hi/CCR5+ CD4+ T cells than EBF in both CM and EM subsets (p<0.05). Within the β7hi EM subset, NX had higher frequency of activated cells (p=0.03). In the CD8+ T cell population, β7hi CM cells were also higher frequency in NX compared to EBF, as were activated cells in each memory phenotype (p<0.01).

Conclusions: Non-exclusively breastfed infants had altered frequencies of CD4 and CD8 T cell subsets compared to EBF infants. The higher frequencies of CCR5+, gut-homing, memory CD4+ T cells, thought to be prime targets for HIV, might contribute to the higher transmission rate associated with mixed breastfeeding.
872 Infant Variants Require More CD4 for Entry Than Maternal Variants Regardless of Transmission Route
Kyle J. Nakamura1, Edwin R. Sobrera1, Vicken Khatchadourian1, Moses Sinkala2, Chihepo Kankasa3, Donald M. Thea4, James I. Mullins4, Louise Kuhn5, Grace M. Aldrovandi6
1Infectious Diseases, Children’s Hospital Los Angeles, Los Angeles, CA, United States, 2Catholic Medical Missions Board, Lusaka, Zambia, 3University Teaching Hospital, Lusaka, Zambia, 4Boston University School of Public Health, Boston, MA, United States, 4Department of Microbiology, University of Washington, Seattle, WA, United States, 5Epidemiology, Columbia University, New York, NY, United States

Background: Despite high level, persistent exposure to virus, the majority of children born to chronically HIV-infected women escape infection. Most infections that do occur are initiated by a single genetic variant selected from a diverse quasi-species swarm. Given the relative paucity of activated, HIV-susceptible CD4+ target cells, particularly in the fetus, we sought to determine the minimum level of CD4 expression required for cell entry by early-transmitted isolates, and whether we could find evidence for selective transmission of variants particularly adept at utilizing low levels of CD4 (such as is present on macrophages) for productive infection.

Methodology: Pseudotype viruses were produced in 293T/17 cells using standard techniques. Affinofile cells, a 293 variant with independently inducible CD4 and CCR5 expression systems and an HIV-inducible secreted luciferase reporter, were treated to maximize expression of CCR5 while CD4 was varied across an ~2 log10 gradient. Infection was normalized as a percentage of entry under saturating CD4 conditions. Percent entry was then plotted by absolute number of CD4 molecules per cell to generate an infection curve. Infection curves were used to back-calculate the number of CD4 molecules/cell necessary to achieve 20% of maximal entry (EC20) for each viral variant. EC20s for epidemiologically linked mother-infant transmission pairs were then analyzed using the GEE model.

Results: EC20 values were generated for 160 unique envelope clones from 7 in utero and 11 breast milk transmission pairs. Regardless of transmission route, infant variants required more CD4 molecules/cell to achieve entry as measured by EC20 (p<0.0001). There were no differences in EC20 between variants from infants infected in utero or by breastfeeding (p=0.7228), or between variants from the transmitting mothers in each group (p=0.7340).

Conclusions: Our data indicate that vertical transmission of HIV does not select for highly efficient usage of CD4, and in fact may require the presence of susceptible target cells with relatively high CD4 expression for either initiation or propagation of infection. Given the lack of route specificity, the described selection is likely not occurring at the site of initial barrier breach (e.g. placenta or gut epithelium), and may represent a common pathway of amplification/outgrowth required for efficient dissemination following the initial seeding event. Our data also support a role for transient inflammation in enhancing fetal/infant susceptibility to infection.

Characteristics of Pregnant Women in PMTCT

873 HIV Viral Load and CD4 Cell Count in Untreated Pregnant Women Entering Care in Cape Town, South Africa
Landon Myer1, Tamara Phillips1, Marvin Hsiad2, Allison Zerbe3, James McIntyre4, Linda-Gail Bekker4, Elaine Abrams5
1Division of Epidemiology & Biostatistics, University of Cape Town, Cape Town, South Africa, 2Division of Virology, University of Cape Town, Cape Town, South Africa, 3ICAP, Columbia University, New York, NY, United States, 4Avbob Health Institute, Johannesburg, South Africa, 4Desmond Tutu HIV Centre, University of Cape Town, Cape Town, South Africa

Background: In many parts of sub-Saharan Africa, CD4+ cell counts are used to determine eligibility for triple-drug antiretroviral therapy (ART) regimens in HIV-infected pregnant women. There is widespread interest in policies for the universal use of ART in pregnancy, regardless of CD4+ count, to reduce viraemia and the subsequent risks of both vertical and horizontal HIV transmission. Yet there are few data on the distribution of HIV viral loads in untreated HIV-infected pregnant women before antiretroviral exposure, and the correlation between viraemia and CD4+ cell counts that may be used to define ART eligibility.

Methodology: We measured HIV viral loads (VL) in consecutive HIV-infected pregnant women, not already on ART or antiretroviral prophylaxis, making their first visit to services for the prevention of mother-to-child HIV transmission (PMTCT) at a large urban antenatal clinic in Cape Town, South Africa. Specimens for VL (Abbott RealTime HIV-1 assay) and CD4+ cell count via flow cytometry (Beckman Coulter) were taken before initiating antiretrovirals. Socio-demographic characteristics and medical history were taken from structured interviews and clinical/laboratory record reviews.

Results: Among 398 women initiating PMTCT between April and September 2013, the median age and gestational age were 28 years (IQR, 24-32) and 21 weeks (IQR, 16-26), respectively; 52% of women were newly diagnosed with HIV in the current pregnancy. The median VL was 3.9 log10 copies/mL (IQR, 3.4-4.5); 8% of women (n=33) had >100,000 copies/mL, 15% (n=62) had 500 cells/μL, respectively (Table). 21 weeks (IQR, 16-26) respectively; 52% of women were newly diagnosed with HIV in the current pregnancy. The median VL was 3.9 log10 copies/mL

Conclusions: A substantial proportion of HIV-infected pregnant women in this setting have high viral loads and are at high risk of both mother-to-child and sexual HIV transmission, but also have raised CD4+ cell counts that would make them ineligible for triple-drug antiretroviral regimens under many policies. As efforts to optimize PMTCT services and eliminate paediatric HIV infection expand across Africa, these data point to potential limitations of strategies that use CD4-based criteria to define ART eligibility for pregnant women.

Detectable Viraemia Among Pregnant Women On Antiretroviral Therapy Initiating Antenatal Care

Landon Myer1, Tamsin Phillips2, Allison Zerbe2, Marvin Hsiao2, James McIntyre4, Elaine Abrams2
1Division of Epidemiology & Biostatistics, University of Cape Town, Cape Town, South Africa, 2ICAP, Columbia University, New York, NY, United States, 3Division of Virology, University of Cape Town, Cape Town, South Africa, 4Anova Health Institute, Johannesburg, South Africa

Background: Services for preventing mother-to-child transmission (PMTCT) of HIV in sub-Saharan Africa typically focus on identifying HIV infection and initiating antiretroviral regimens in pregnant women who are not already in care. However significant increases in antiretroviral therapy (ART) uptake across the region mean that a growing number of HIV-infected women conceive and initiate antenatal care already on ART. Women conceiving on ART are presumed to be virally suppressed throughout pregnancy, and thus at minimal risk of vertical HIV transmission, but there are few data on viraemia in pregnancy in women conceiving on ART in African settings.

Methodology: Working in a large primary care antenatal clinic (ANC) in Cape Town, South Africa, we conducted a cross-sectional study of consecutive HIV-infected pregnant women who had started ART before conception. We examined the prevalence and correlates of viraemia, defined in separate analyses as >50 copies/mL (Abbott RealTime HIV-1) and >1000 copies/mL (as vertical transmission risk increases above this level).

Results: Between April and September 2013, 210 women reported current use of ART at their first ANC/PMTCT visit, representing 35% of all HIV-infected pregnant women attending the service. The median duration of ART use before pregnancy was 2.7 years (IQR, 1.4-5.2). The majority of ART regimens (69%) were tenofovir, lamivudine and either efavirenz (50%) or nevirapine (19%); and additional 13% of women were on a second-line regimen based on protease inhibitors (PI). Twenty percent reported missing ART doses on at least 2 days during the preceding month. Overall 167 (81%) of women had 10,000 copies/mL, respectively. In logistic regression models, there were no significant demographic or clinical predictors of viraemia at either >50 or >1000 copies/mL, including age, gravidity, gestation, regimen or duration of ART use. However women with viral loads >1000 copies/mL were more than twice as likely to report missing 2 or more doses in the preceding 30 days, compared to women who were suppressed (p=0.025).

Conclusions: These data demonstrate a surprisingly high prevalence of detectable viraemia among pregnant women entering PMTCT services already on ART, representing a vertical transmission risk that is not well understood in African ART programmes. With increasing numbers of HIV-infected women of reproductive age receiving lifelong ART (more than one-third in this setting) there is an urgent need to investigate the causes of viraemia in this group of patients and in turn develop strategies to intervene to reduce viral load rapidly in these women.

Steady Decline: Temporal Changes in Substance Use by HIV-Positive Pregnant Women in the US

Kathryn Rough1, Katherine Tsaiopoulos2, Deborah Kacanek3, Raymond Griner3, Ram Yogev4, Kenneth C. Rich5, George R. Seage1, for the Pediatric HIV/AIDS Cohort Study 1Department of Epidemiology, Harvard School of Public Health, Boston, MA, United States, 2Center for Biostatistics in AIDS Research, Harvard School of Public Health, Boston, MA, United States, 3Department of Epidemiology, Biostatistics, and Occupational Health, McGill University School of Medicine, Montreal, QC, Canada, 4Ann & Robert H. Lurie Children’s Hospital, Chicago, IL, United States, 5University of Illinois at Chicago, Chicago, IL, United States

Background: Substance use during pregnancy has implications for HIV transmission, infant outcomes, and maternal outcomes. This study describes changes in and correlates of substance use during pregnancy from 1990-2012 in two US-based cohorts of HIV-infected women.

Methodology: All women enrolled in the Women and Infants Transmission Study (WITS) and the Pediatric HIV/AIDS Cohort Study’s Surveillance Monitoring for ART Toxicities Study (SMARTT) who gave birth from 1990-2012 and had available substance use information were included. Women were classified as using a substance during pregnancy if they self-reported or had a positive biological sample (urine in WITS or meconium in SMARTT) for alcohol, tobacco, marijuana, cocaine, or heroin use. Log binomial generalized estimating equations (GEE) were used to test for temporal trends and account for correlation between repeated pregnancies by the same woman. Predictors of substance use were evaluated using a multivariable logistic GEE.

Results: Over the duration of the study, substance use among the 5,451 enrolled women sharply declined; 82% of women reported substance use during pregnancy in 1990, compared to 23% in 2012 (Figure 1). During the 22-year period, use of each substance decreased significantly (p<.001 for each substance) in an approximately linear fashion, until reaching a plateau in 2006. In the subset of 824 women with multiple pregnancies under study observation, substance use did not significantly decrease with successive pregnancies. Women who used a substance during the previous pregnancy were 5.45 times more likely (95% Confidence Interval: 4.46, 6.67) to use a substance during their next pregnancy. In the HAART era (1996 - 2012), White race, older age, less education, being unmarried, and not taking antiretroviral medications were associated with an increased risk of using substances during pregnancy.

Conclusions: A substantial decrease in substance use during pregnancy was observed between 1990 and 2012 in two large US cohorts of HIV-infected women. The observed decrease may largely be due to the HIV/AIDS epidemic becoming more generalized in the US population in recent years. Our data also suggest that HIV-infected women who used substances during previous pregnancies are at an increased risk of using substances in future pregnancies, and may be a target for future interventions.

Figure 1. Substance use during pregnancy by year of delivery (N= 5,451)
Modeling the Performance and Cost of Early Infant HIV Diagnosis at Birth

Intira J. Collins¹, Martina Penazzato¹, Dick Chamla¹, Anisa Ghadrshenas¹, Teri Roberts¹, Jennifer Cohn¹, Nicole Ngo-Giang-Huong¹, Nathan Shaffer¹, Meg Doherty¹, Lisa J. Nelson¹
¹MRC Clinical Trials Unit, London, United Kingdom, ²HIV Department, World Health Organization, Geneva, Switzerland, ³UNICEF, New York, NY, United States, ⁴Clinton Health Access Initiative, Nairobi, Kenya, ⁵Médecins sans Frontiéres, Geneva, Switzerland, ⁶Programs for HIV Prevention and Treatment (IRD-PHPT), Chiang Mai, Thailand

Background: Untreated HIV-infected infants are at high risk of death in the first year of life. WHO recommends early infant diagnosis (EID) using virological testing (VT) from 6 weeks, but coverage is poor. Testing at birth (BT) was hypothesized to improve EID coverage and reduce mortality by earlier initiation of ART, although VT has poorer sensitivity at birth. We modelled the performance and cost of BT against the current WHO algorithm. We present preliminary results of the model applied to South Africa.

Methodology: A decision tree cohort simulation model was developed and applied to infants born in a prevention of mother to child transmission of HIV (PMTCT) program setting. Infants enter the model at birth with a risk of in-utero, intra- and post-partum transmission. In the BT algorithm, children are tested at birth (0-3 days), 12 wks, 9 and 18 months vs. testing at 6 wks, 9 and 18 months in the WHO algorithm. Both algorithms include testing at end of breastfeeding. The model runs up to 24 months of age. HIV-infected children have a probability of diagnosis, referral for HIV care, ART initiation or pre-ART death (Table 1). Outcomes of interest were positive predictive value (PPV), negative predictive value (NPV) of VT, cost per diagnosis, proportion of HIV-infected children correctly diagnosed, initiated on ART and pre-ART deaths.

Results: PPV and NPV was 88.5% and 97.6% in BT and 90.8% and 97.6% in the WHO algorithm, respectively. Cost per HIV-infected diagnosis was $1,379 and $458, respectively. The proportion of HIV-infected children diagnosed by 24 months was 69.2% in BT vs 54.9% in WHO algorithm. However, the proportion of HIV-infected children starting ART was more comparable at 37.0% vs 32.4%; and pre-ART deaths was 24.9% vs 26.7% respectively. In scenario analyses, assuming improved EID coverage, retention and referral for ART (90%) the proportion starting ART rose to 70.2% vs. 68.5%, and pre-ART deaths fell to 17.1% and 18.1% respectively. In contrast, if we assumed current coverage/referral rates but higher sensitivity of BT (98%), the proportion of HIV-infected diagnosed rose to 75.2%, but with modest improvements in proportions starting ART(40.7%) and pre-ART death (23.1%).

Conclusions: EID at birth would potentially increase the proportion of HIV-infected children diagnosed, but has lower PPV; if not accompanied by improved retention and referral for ART, it offers limited improvements in proportion starting ART or in reducing pre-ART mortality.

877 Access To Early Diagnosis and Antiretroviral Therapy in Abidjan, Côte d’Ivoire, 2011-2013
Divine Avit1, Madeleine Folquet-Amorsissi2, Clarisse Amari-Bosse1, Jeanne Elam-Kouakou3, Véronique Mba-Assandé2, Edmond Akia4, Irna Ahoba2, Didier K. Ekouévi3, Marguerite Timité-Konan4, Valériane Leroy5, 6, for the MONOD ANRS 12206 Study Group

Background: Since 2010, the routine initiation of early antiretroviral therapy (ART) is recommended by WHO for all HIV-infected children younger than two years old. The national Ivorian program decided to scale-up the early infant diagnosis (EID) of HIV using Dried Blood Spot (DBS) in 2011. We described the access to pediatric HIV EID results and pediatric ART in Abidjan, Côte d’Ivoire.

Methodology: In the context of the recruitment in the MONOD ANRS 12206 trial, a survey of the tools and timing used for EID, and the access to ART for all the children identified as HIV-infected before the age of two, was conducted in 29 health centers in Abidjan from September 2011 to January 2013. The rate of announcement of EID results, and the subsequent access to ART before the age of two for those HIV-infected were studied; barriers were described and the correlates of early access to ART analyzed using a logistic regression model.

Results: A total of 2397 HIV-exposed infants under 12 months had access to an EID based on “Dried Blood Spot”. Their test results were returned to the sites in 77.2% of cases and announced to their family in 58.7% of cases. Out of the 226 children confirmed as HIV-infected<2 years of age, 80.3% were identified by PCR DNA on DBS before 12 months of age, 4.8% by PCR DNA at 12-18 months and 14.9% by serology after 18 months. Before the age of two, 148 children were initiated on ART: the ART coverage was 64.6% (95% CI [59.3%-71.7%]) of which 70.0% via the inclusion in the Monod trial. The missed opportunities of access to ART (34.4%) were due to the early death of the child (57.7%), the parental refusal of ART (30.8%) and the loss to follow-up of children (11.5%). The age of the child>12 months at diagnosis (adjusted odds ratio [aOR]:4.2;95% CI:1.6-11.0), a maternal age>30 years (aOR:2.4;95% CI:1.2-4.9), the parental access to ART for their own health (aOR:2.6;95% CI:1.2-5.6) were independently significantly associated with a higher access to early initiation of pediatric ART, while “an unknown HIV status for himself or his child” declared by the father was associated with a lower access to ART (aOR:0.2;95% CI:0.1-0.5).

Conclusions: Although pediatric access to ART is feasible, there are still remaining too many missed opportunities to cover the access to ART needs before 2 years of age in 2011-2013. Challenges still remain to improve early diagnosis of HIV-infected infants at the earliest available, and to promote a continuum of care for HIV-infected children before they die. With the commitment of the National Program, it is crucial to identify sustainable mechanisms to promote an early access to infant HIV care services within a family approach in Côte d’Ivoire.

878 Impact of Maternal Incident HIV Infection On Early HIV Vertical Transmission, South Africa in 2011
Thu-Ha Dinh1, Kevin Delaney1, Debra Jackson2, Salam Woldesenbet3, Yogay Pillay4, Ameena Gogo5
1Centers for Disease Control and Prevention, Atlanta, GA, United States, 2School of Public Health, University of the Western Cape, Cape Town, South Africa, 3South Africa Medical Research Council, Cape Town, South Africa, 4National Department of Health, Pretoria, South Africa, 5South Africa Medical Research Council, Pretoria, South Africa

Background: We used data from a nationally representative evaluation of the South African prevention of MTCT program to estimate the risk of maternal incident HIV infection during pregnancy on early MTCT risk in South Africa (SA) in 2011-2012.

Methodology: We recruited mothers and their 4-8 week old infants from 578 primary health facilities using a stratified multi-stage sampling design from August 2011 to March 2012. Mothers were interviewed and infant dried blood spot samples (iDBS) were collected and tested for presence of HIV antibody and HIV DNA. Maternal incident HIV infection during pregnancy was defined as an HIV antibody positive result on iDBS of an infant whose mother reported having a negative HIV test result and had no evidence of receiving antiretroviral (ARV) drugs when pregnant with the infant. We used a uniform distribution of the time between delivery and last reported negative HIV test result during the pregnancy to estimate gestational age at infection. Estimates are adjusted for nonresponses and weighted by 2011’s live births in SA.

Results: Of 9802 mother-infant pairs included in the current analysis, 7064 infants tested HIV antibody negative and 2738 HIV antibody positive on iDBS indicating the mother was HIV infected when pregnant with the infant. The latter includes 212 maternal incident HIV infections. This results in a weighted national estimate of 3.1% maternal incident HIV infection. Median time of incident infection was at 32.1 weeks gestation (95% confidence interval (CI) 31.4-33.4wks) with 23.6% occurring between 32-36 weeks and 27.4% after 36 weeks gestation. Mother to Child Transmission of HIV (MTCT) risk was 10.7% (95% CI: 6.2% - 16.8%) for mothers with incident infection compared to 2.2% (95% CI: 1.6% - 2.8%) for mothers already HIV infected. Although they represent only 2.2% of all mothers (n=9802), and 6.7% of HIV-infected mothers, mothers with incident infection accounted for 26% of early MTCT risk. Multivariable analysis indicates incident infection was highest for women who reported the baby’s father was HIV infected (Adjusted Odds Ratio (AOR) =6.2, p<0.05) compared to those that knew the baby’s father was uninfected), while each additional follow-up antenatal care visit reduced incident infection (AOR=0.92, p<0.05)

Conclusions: Maternal incident HIV infection during pregnancy is high and contributes to a significant burden of newly HIV infected infants in SA. Repeat-testing at 32 weeks gestation, during labor and 6 weeks postpartum will identify mothers with incident infection who should receive ARV therapy (ART) to reduce MTCT risk. Couple counseling and providing ART to HIV positive male partners of HIV-negative women seeking to become pregnant could also reduce maternal incident HIV infection and MTCT.
Syphilis in HIV-Infected Mothers and Infants: Results From the NICHD/HPTN 040 Study

Nava Yeganeh,1 Heather Watts,2 Margaret Camarca,3 Esaú Joao,3 Jose Henrique Pilotto,3 Glenda Gray,4 Gerhard Therou,3 Valdilea G. Veloso,5 Lynne M. Mofenson,1 Karin Nielsen-Saines,1 NICHD HPTN 040/P1043 Study Team

Background: The HIV and syphilis epidemics overlap, particularly in low and middle-income countries. Over 1 million pregnancies are complicated by congenital syphilis annually. Untreated maternal syphilis is associated with spontaneous abortion, stillbirth, prematurity, and neonatal and infant mortality.

Methodology: We evaluated data available from 1664 mothers and 1684 infants enrolled in NICHD/HPTN 040 (P1043), a study focused on prevention of intrapartum HIV transmission to infants born to HIV-infected mothers who did not receive antiretrovirals prior to labor. Univariate and multivariable logistic regression were performed to determine predictors of maternal syphilis and the occurrence of congenital syphilis in their newborns.

Results: One hundred seventy-one HIV-infected women enrolled in NICHD/HPTN 040 (~10% of the cohort) had serological evidence of syphilis without adequate documentation of treatment during pregnancy. One hundred thirty-two women had reactive non-treponemal serologies with confirmatory treponemal tests while 39 women had a positive non-treponemal test with no confirmatory testing performed. One hundred and twenty infants were treated for congenital syphilis during the study, with 24 infants treated for both HIV and syphilis. Multivariate analysis demonstrated that dually-infected women were significantly more likely to self-identify as non-white (AOR 2.5, 95% CI 1.5-4.2) and to drink alcohol during pregnancy (AOR 1.5, 95% CI 1-2.1). Dually-infected women were also twice as likely to transmit HIV to their infants (AOR 2.1, 95% CI 1.3-3.4), with 88% of HIV infections in these children acquired in utero. Co-infected infants were significantly more likely to be born to mothers with VDRL titers $\geq$1:16 (AOR 3, 95% CI 1.1-8.2) and higher HIV viral loads (AOR 1.5 95% CI 1.1-1.9). Of 6 newborns with symptomatic syphilis, 2 expired shortly after birth, and 2 were HIV-infected.

Conclusions: Syphilis continues to be a common co-infection in HIV-infected women and is associated with a higher likelihood of in utero HIV transmission. Prompt recognition of syphilis infection in HIV-infected women is necessary to avoid adverse pregnancy outcomes, including HIV in utero transmission or fetal/neonatal death. While most neonates with congenital syphilis are asymptomatic at birth, symptomatic disease is associated with high morbidity and mortality.

Antiretroviral Adherence Associated With Reduced Breastmilk HIV-1 Transmission: The BAN Study

Nicole L. Davis,1 William C. Miller,1 Michael G. Hudgens1, Charles S. Chasela,1 Dorothy S. Sichiali3, Dumbani Kayira4, Athena P. Kourtis3, Sascha R. Ellington1, Denise J. Jamieson2, Charles M. van der Horst6
1Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 2Epidemiology, Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 3Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 4University of North Carolina Project, Lilongwe, Malawi; 5Division of Reproductive Health, Centers for Disease Control and Prevention, Atlanta, GA, United States; 6Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Background: Postnatal HIV-1 transmission occurred in the Breastfeeding, Antiretrovirals and Nutrition (BAN) study despite well-controlled implementation of either maternal antiretrovirals (ARV) or daily infant nevirapine (NVP) throughout 28 weeks of breastfeeding. One possible explanation for transmission is suboptimal adherence to prescribed antiretrovirals. Quantifying the association between adherence and breastmilk HIV-1 transmission will have significant practical implications for elimination of mother-to-child HIV transmission efforts.

Methodology: We included mother-infant pairs randomized to receive 28 weeks of either maternal ARV (Zidovudine, lamivudine, and either nevirapine, nelfinavir, or Kaletra©) or daily infant NVP as part of the BAN study. Using extended Cox models, we estimated associations between postpartum ARV adherence and breastmilk HIV-1 transmission between 5-38 weeks of age. We measured adherence over four time intervals between 2-28 weeks postpartum using pill count, suspension bottle weight, and maternal self-report. We used multiple imputation to account for missing adherence measures. Infant HIV infection was determined by polymerase chain reaction every 2-6 weeks using the Roche Amplicor 1.5 DNA assay. The primary endpoint was infant HIV infection by 38 weeks of age among infants alive and uninfected at 5 weeks, with censoring at loss to follow-up.

Results: 1477 mother-infant pairs were included in analyses. Using pill count and bottle weight information, 22-40% of mother-infant pairs at any given interval were < 90% adherent. Between 5-10% of mothers at any given interval self-reported missing at least one dose of maternal or infant ARV medication over the last three days. Having $\geq$ 90% pill count or bottle weight adherence was associated with a 56% (95% CI 12-78%) relative reduction in the rate of HIV-1 transmission by 38 weeks of age, compared with having < 90% adherence when controlling for study arm, time-dependent reported breastfeeding status, and maternal baseline characteristics, including age, CD4+ count, and hemoglobin level. Reporting missing no pills in the prior 3 days (100% self-reported adherence) was associated with a 66% (95% CI 14-86%) relative reduction in the adjusted rate of HIV-1 transmission, compared with those self-reporting < 100% adherence during the prior 3 days. Complete case analyses rendered similar results (pill count or bottle weight: n=500, adjusted HR 0.41, 95% CI 0.18-0.93; self-report: n=540, adjusted HR 0.26, 95% CI 0.09-0.72).

Conclusions: Maintaining adherence to postpartum ARVs throughout breastfeeding is important for elimination of mother-to-child transmission. More work is needed to identify patients likely to be non-adherent, and to intervene before HIV transmission occurs.
Cytomegalovirus and Possibly Epstein-Barr Virus in Breast Milk May Facilitate HIV-1 Transmission

Johannes Viljoen1, Edward Tsuﻺl1, Nicolas Nagot2, Siva Danaviah3, Marianne Peries4, Prevashinee Padayach5, Vincent Foulonne6, Ruth Bland7, Nigel Rollins8, Marie-Louise Nweli9, Philippe Van de Perre2

1Africa Centre for Health and Population Studies, University of KwaZulu-Natal, Durban, South Africa, 2CHRU de Montpellier, Département de Bactériologie-Virologie, Université Montpellier 1, Montpellier, France, 3Department of Paediatrics & Child Health, University of KwaZulu-Natal, Durban, South Africa

**Background:** HIV-1 mother-to-child transmission (MTCT) occurs despite antiretroviral treatment (ART), including through breastfeeding, although the exact mechanisms remain largely unknown. Since the vast majority of breastfed infants of HIV-1 infected mothers escape infection even in the absence of ART, some factors must drive HIV-1 transmission by breastfeeding. Co-infections including Cytomegalovirus (CMV) and Epstein-Barr virus (EBV), may be associated with increased risk of HIV-1 MTCT through mechanisms enhancing reciprocal viral replication. Here we report the findings of a case-control study that investigated the relationship between CMV DNA levels and EBV DNA detection in breast milk (BM) and the risk of MTCT of HIV-1 via breastfeeding.

**Methodology:** Active subjects were 62 mothers with established HIV-1 infection and proven postnatal transmission of HIV-1 via breastfeeding (transmitters), matched by non-transmitter controls. Cell-free HIV-1 RNA, cell-associated HIV-1 DNA, CMV and EBV DNA were quantified in breast-milk (BM) and their association with MTCT of HIV-1 determined. Samples immediately prior to the estimated timing of transmission of HIV-1 were used.

**Results:** Maternal HIV-1 RNA plasma viral load was significantly higher in transmitters (4.5 log10 copies/ml) [IQR 3.9-4.8] than in controls (3.8 log10 copies/ml) [IQR 3.1-4.4] (p=0.003) and there was a trend towards lower CD4 counts; median (IQR) BM HIV-1 DNA level was similarly higher in transmitters, 5002 (1993-14890) than in controls, 280 (280-461.5) copies/106 BM cells. Median CMV DNA viral load was significantly higher in transmitters (median 88044 DNA copies/106 BM cells; IQR 18586-233904) than controls (median 11167; IQR 3221-31152) (p<0.001). Breast milk CMV DNA load was associated with maternal CD4 depletion in blood (p<0.001) CMV DNA viral load in BM was significantly associated with post-natal MTCT of HIV-1 with a &gt;2-fold risk of MTCT with every 1 log increase in CMV DNA level. This risk was independent of HIV-1 RNA levels in milk. EBV DNA detection in BM may also facilitate MTCT of HIV-1, but only marginally.

**Conclusions:** This study provides evidence of an independent association between CMV DNA in BM, and additionally a marginal association between EBV DNA in BM, and postnatal MTCT of HIV-1, while confirming previous findings that HIV-1 RNA and DNA levels in breast-milk are strongly predictive of postnatal transmission of HIV-1. The demonstrated association between CMV and EBV DNA and HIV-1 levels in BM in this study may explain persistent shedding of HIV-1 in BM in women receiving ART. Valacyclovir as a potential adjuvant to ART to reduce MTCT of HIV-1 during the period of breastfeeding is an interesting concept that would require further study.

**PMTCT Approaches: Implementation and Outcome**

882 Programmatic Implementation of WHO Option B in Botswana Associated With Increased Projected MTCT

Scott Dryden-Peterson1,2, Sajini Souda3, Rebecca Zash4, Jennifer Chen5, Chipo Petlo6, Eldad N. Dintwa4, Refelteetswe Lebelonyane4, Mopamotse Mmalane4, Shahin Lockman3,5,6, Roger L. Shapiro1,2

1Department of Medicine, Brigham & Women’s Hospital, Boston, MA, United States, 2Botswana Harvard AIDS Institute, Gaborone, Botswana, 3University of Botswana, Gaborone, Botswana, 4Department of Medicine, Beth Israel Deaconess Medical Center, Boston, MA, United States, 5Department of Medicine, Massachusetts General Hospital, Boston, MA, United States, 6Ministry of Health, Gaborone, Botswana

**Background:** The 2013 WHO guidelines for prevention of mother-to-child transmission (PMTCT) recommend that countries offering antenatal zidovudine (Option A) transition to 3-drug antiretroviral treatment (ART) for all pregnant women, regardless of CD4 count (Option B or B+). In 2009, Botswana became one of the first African countries to transition from WHO Option A to Option B. Although midwives at antenatal clinics administered Option A, women were referred to ART clinics to start ART under Option B. We evaluated the impact of this transition on projected MTCT.

**Methodology:** From May 2009 to October 2012, covering both the initial pilot in selected regions and the general roll-out of Option B, we abstracted all obstetric records at 6 of the busiest maternity wards in Botswana to determine the PMTCT interventions received in pregnancy and at the time of delivery. We used published estimates for MTCT rates by maternal CD4 strata and interventions received to assign an MTCT prevention score (MPS) to each delivery. Multivariable regression accounting for clustering was used to estimate the impact of Option B on the MPS while adjusting for maternal and facility characteristics.

**Results:** Of 36597 Botswana citizens delivering, 29.7% were HIV infected, 69.1% were HIV-uninfected, and 1.2% had undocumented HIV status. Among 10867 HIV-infected women, 27.2% started ART prior to pregnancy and 72.8% were ART-naïve. Of ART-naïve women, 65.2% entered antenatal care at a clinic offering Option A and 34.8% at a clinic offering referral for Option B (an onsite ART clinic was available to provide Option B for 65.3% of women). Trends in antiretroviral use and MPS are shown in Figures 1 and 2. In adjusted analyses, registering at a clinic offering referral for Option B was associated with increased ART use (adjusted odds ratio [aOR] 2.05, 95% confidence interval [CI] 2.32 to 3.10), but also an increased likelihood of no antenatal antiretroviral use by the time of delivery (aOR 2.05, 95%CI 1.69 to 2.47). Overall, in the first 3 years of the program, Option B implementation was significantly associated with higher projected MTCT rate. MPS +0.14 (P<0.001).

**Conclusions:** Implementation of Option B in Botswana was associated with an overall increased projected MTCT rate, due to increased numbers of women receiving no antenatal antiretrovirals. Programs starting Option B or B+ should ensure that ART is initiated at antenatal clinics and that zidovudine monotherapy remains an available option in the event of delayed ART initiation.
Impact of Option B+ On Uptake, Retention, and Transmission: A Pre/Post Study in Lilongwe, Malawi
Maria H. Kim1, 2, Saeed Ahmed1, 2, Peter N. Kazembe1, Mina C. Hosseinipour1, 3, Thomas P. Giordano3, Elizabeth Y. Chiao3, Xiaoying Yu6, Debora Nanthuru2, Mary E. Paul1, Elaine J. Abrams7
1Baylor College of Medicine, Texas Children’s Hospital, Houston, TX, United States, 2Baylor College of Medicine-Abbott Fund Children’s Clinical Center of Excellence, Lilongwe, Malawi, 3UNC Project, Lilongwe, Malawi, 4University of North Carolina School of Medicine, Chapel Hill, NC, United States, 5Department of Medicine, Baylor College of Medicine, Houston, TX, United States, 6Department of Pediatrics, Epidemiology Center, Baylor College of Medicine, Houston, TX, United States, 7ICAP, Mailman School of Public Health, Columbia University, New York, NY, United States

Background: In September 2011, Malawi implemented Option B+ (B+), lifelong antiretroviral therapy (ART) for pregnant and breast feeding women. The Tingathe program, started in 2009, two years prior to B+, is a service program utilizing dedicated community health workers (CHWs) as case managers to improve uptake and retention along the PMTCT cascade. The service is offered as part of routine care at participating government health centers. We assessed the impact of B+ on service uptake, retention, and vertical HIV transmission by comparing outcomes pre and post B+ implementation at 2 health centers in Lilongwe.

Methodology: PMTCT service utilization, program retention, and transmission outcomes at 1st DNA PCR (4-20 wks of age) were compared for HIV-infected (HIV+) pregnant women and their exposed infants followed in Tingathe 18 months pre (Oct 2009-Mar 2011) and post (Oct 2011-Mar 2013) B+. Chi-square and Fisher’s exact test as well as two-sample t-test were used to compare proportions of events and continuous variables, respectively.

Results: A total of 13,926 (pre) and 14,022 (post) women presented to antenatal care. Post B+ a smaller proportion of women were HIV tested (98.9% pre vs 83.4% post; p<0.001); attributed to test kit stock-outs. There were 1654 (pre) and 1535 (post) HIV+ women identified, with a larger proportion already known to be HIV+ (18.1% vs 41.2%; p<0.001) and an increase in the proportion of women already on ART at B+ (22.8% vs 31.1%; p<0.001). Of those starting ART, mean time to ART initiation (38 ± 32 vs 19.7 ± 47 days; p<0.001) and duration on ART prior to delivery (69 ± 43 vs 93 ± 46.5 days; p<0.001) improved significantly. Amongst recorded live births there was no change in proportion of women (95.6% vs 96.3%; p=0.45) and infants receiving antiretrovirals for PMTCT (96.3% vs 95.3%; p=0.11) nor infants receiving 1st DNA PCR (80.9% vs 82%; p=0.55). However, other outcomes suggest improvements in infant care post B+: mean age at 1st DNA PCR (70 ± 45 pre vs 57 ± 31 days post; p<0.001) and transmission at 1st DNA PCR was lower (4.6% pre vs 2.6% post; p=0.046); proportion of HIV+ infants starting ART was greater (78.1% vs 90%; p=0.45); mean age at initiation was lower (171 ± 88 vs 118 ± 76 days; p=0.046).

Conclusions: Patient level data from a CHW supported program in Lilongwe, Malawi demonstrate that B+’s simplified PMTCT approach has resulted in several improvements including improved ART use during pregnancy and more rapid initiation with longer duration of coverage for those newly initiating. Early findings suggest concomitant improvements in infant care along the cascade. Health systems issues like timely and reliable HIV testing for women and infants, continue to greatly impact implementation and will need to be addressed to ensure an AIDS-free generation.

Home, Antenatal Clinic or VCT: Preferences of Pregnant Women and Their Partners for Male HIV Testing
Alfred Osoti1, 2, Grace John-Stewart1, James Kairie1, John Kinuthia1, Barbra Richardson1, Daisy Krakowiak1, Carey Farquhar6
1Epidemiology, University of Washington, Seattle, WA, United States, 2Obstetrics and gynecology, University of Nairobi, Nairobi, Kenya, 3Epidemiology, Pediatrics, Medicine, Global Health, University of Washington, Seattle, WA, United States, 4Obstetrics and Gynecology, University of Nairobi, Nairobi, Kenya, 5Research, Kenya National Hospital, Nairobi, Kenya, 6Epidemiology, Medicine, Global Health, University of Washington, Seattle, WA, United States

Background: Male partner HIV testing and counseling (HTC) enhances prevention of mother to child HIV transmission (PMTCT), yet male HTC during pregnancy remains low. Identifying male HTC models preferred by pregnant women and their male partners might improve male partner uptake of HIV testing and involvement in maternal and child health.
**Methodology:** In a randomized clinical trial of home-based versus clinic-based male partner HTC to improve male partner testing during pregnancy, pregnant women and their male partners were interviewed to determine the preferred location for male partner testing as either home-based, at a voluntary counseling and testing center (VCT) or antenatal care (ANC) clinic. Proportions of women and their partners who preferred each testing model were determined at baseline and then compared 6 weeks after the intervention using McNemar's tests.

**Results:** Three hundred women were randomized, 150 to home-based and 150 to ANC clinic based male partner HTC. At enrolment, the majority (54%) stated they would prefer home-based to ANC clinic based (34%) or VCT based (12%) male partner HTC. Overall, post-intervention, the proportion of women preferring home-based HTC increased (65% vs 54%; odds ratio [OR] 1.90 95% confidence interval [CI] 1.26-2.89; p = 0.001), while the proportion preferring male partner testing at the ANC clinic (25% vs 34%; OR 0.60 CI 0.35-0.87; p = 0.007) or VCT (9% vs 12%; p = 0.258) decreased.

At enrollment, 95 (71%) of 133 male partners reached at home compared to 33 (60%) of 55 male partners who came to the clinic preferred home-based HTC. Following the intervention, majority of men 116 (87%) reached at home were significantly more likely to recommend home-based HTC (OR 3.33 95% CI 1.54-7.98; p = 0.001), while more men 36 (65%) tested at the ANC clinic had a non-significant trend towards home-based male partner HTC (OR 1.27 CI 0.54-3.10; p = 0.548). Post intervention, significantly fewer men reached at home recommended male partner testing at the ANC clinic (7% vs 14%; OR 0.41 CI 0.144-1.04; p = 0.041) or VCT (6% vs 14%; OR 0.35 CI 0.11-0.94; p = 0.035). Male partners reached at the clinic post-intervention were less likely to prefer ANC clinic based HTC (24% vs 31%; p = 0.394) but slightly more likely to prefer VCT center HTC (11% vs 9%; p = 0.706), however these changes were not statistically significant.

**Conclusions:** Home-based male partner testing was preferred over VCT based or ANC clinic based testing by both pregnant women and their male partners. Home-based male partner HTC during pregnancy may increase the number of male partners who undergo HTC, and identify HIV negative women in HIV discordant relationships who are at high risk of HIV acquisition and mother-to-child HIV transmission.

### 885 Early Infection Among Ugandan HIV-Exposed Infants Whose Mothers Received Option B+ vs Option A

**Julie N. Mugerva**, Zikulah Namukwaya, Aedreda Kakinwilwa, Albert Maganda, Racheal Ayanga, Ayoub Kakande, Joyce Matovu, Josaphat Byarnugisha, Godfrey Esinu, Mary G. Fowler
1PMTCT, Makerere University-Johns Hopkins Research Collaboration (MU-JHU), Kampala, Uganda, 2Baylor College of Medicine Children’s Foundation-Uganda, Kampala, Uganda, 3Pediatrics and Child Health, Makerere University College of Health Sciences, Kampala, Uganda, 4Obstetrics and Gynaecology, Makerere University College of Health Sciences, Kampala, Uganda, 5PMTCT, Ministry of Health, Kampala, Uganda, 6Johns Hopkins University School of Medicine, Baltimore, MD, United States

**Background:** Interventions with combination antiretroviral (ARV) treatment during pregnancy and breastfeeding have shown significant progress in prevention of mother to child transmission (PMTCT) of HIV. At Mulago Hospital, Uganda, Option A (antenatal zidovudine plus peripartum single dose nevirapine/zidovudine/3TC tail and infant nevirapine throughout breastfeeding) were used from December 2010 for PMTCT. Option B+ (lifelong ART for PMTCT with Tenofovir/3TC/Efavirenz) was rolled out in October 2012

**Methodology:** We compared early (6-12 week) infection rates among infants of HIV+ mothers at Mulago Hospital, Uganda, Option A (antenatal zidovudine plus peripartum single dose nevirapine/zidovudine/3TC tail and infant nevirapine throughout breastfeeding) were used from December 2010 for PMTCT. Option B+ (lifelong ART for PMTCT) with Tenofovir/3TC/Efavirenz was rolled out in October 2012

**Results:** Out of 1015 mothers who received option A for PMTCT, 29 (2.9%) infants tested PCR positive at age 6-12 weeks, compared to 11/586 (1.9%) infants born to mothers who received Option B+. The lowest infection rates were observed for infants whose mothers received ART for their own health; 21/1948 (1.1%) during both time periods.

**Conclusions:** There were no significant differences in early HIV infection rates among HIV exposed infants whose mothers received option B+ compared to those who earlier received option A. Further follow up is needed to ascertain long term adherence, emergence of resistance, and late transmission rates for Option A versus B+ regimens; particularly among asymptomatic HIV + women with higher CD4 counts.

### 886 Lay Health Worker Support To Strengthen PMTCT: A Randomised Controlled Trial in South Africa

**Kathryn Stinson**, Debbie van Zyl, Hlengwi Mabuka, Jean-Pierre Zeelie, Christopher J. Colvin, Leigh F. Johnson, David Coetzee, Helen Schneider
1Centre for Infectious Disease Epidemiology & Research, University of Cape Town, Observatory, South Africa, 2Community Media Trust, Cape Town, South Africa, 3University of the Western Cape, Cape Town, South Africa

**Background:** In South Africa, PMTCT services need to be strengthened to eliminate pediatric HIV by 2015. Lay health workers (LHWs) can play an important role in supporting the continuity of care in primary health care services in developing countries.

**Methodology:** This pragmatic cluster randomised controlled trial assessed the effectiveness of LHWs in reducing missed opportunities at PMTCT services. The study was conducted in the Free State province, South Africa where HIV antenatal prevalence was estimated at 30% in 2011.

*ART: met adult treatment criteria for own health during roll out of option A and option B+*
LHWs at 16 intervention clinics supported pregnant women individually; presented health promotion messages, and assisted with clinic tasks. Sixteen control clinics offered standard PMTCT services. Routine data on PMTCT cascade indicators were collected and verified against paper-based registers and clinical records at all sites, from April 2011 to March 2013. Time series analysis was used to analyse overall trends in the indicators over time, and multivariate logistic regression was used to model the effect of the intervention for each indicator. The main outcome was PMTCT coverage, defined as the proportion of HIV-infected women who received prophylaxis or ART at delivery.

Results: Over 24 months, there was a significant increase in early antenatal presentation; follow-up HIV re-testing rates at 32 weeks and PMTCT coverage across all 32 sites. HIV-negative women who tested were more likely to retest for HIV at 32 weeks at the intervention sites (OR: 1.32, 95% CI: 1.03-1.69, p<0.05). The odds of PMTCT coverage were greater in the intervention sites, however, this outcome was not statistically significant (OR: 1.12, 95% CI: 0.86-1.46). Other PMTCT indicators did not show significant differences between intervention and control arms.

Conclusions: LHWs played a crucial role in supporting, informing and ultimately enabling continuity of care during pregnancy. The increased 32-week re-testing rate in intervention sites suggests LHWs positively influenced continuity of care. The increasing trend in performance across all sites may have been due to external factors, including the prioritization of national PMTCT policy at the time.

ART Pharmacokinetics During Pregnancy and Breast-Feeding

887 Low Darunavir Exposure During Pregnancy With 800/100 mg Darunavir/r QD Dosing
Angela Colbers1, José Moto2, Jelena Ivanovic3, David Hawkins4, Tariq Sadiq5, Kabamba Kabeya4, Andrea Gingelmaier6, Katharina Weizsäcker1, Graham Taylor2, David Burger3

1Department of Pharmacy, Radboud University Medical Center, Nijmegen, Netherlands, 2Lluita contra la Sida Foundation, Hospital Universitari Germans Trias i Pujol, Badalona, Spain, 3National Institute for Infectious Diseases “L. Spallanzani,” Rome, Italy, 4Chelsea & Westminster Hospital, London, United Kingdom, 5St George’s Hospital, London, United Kingdom, 6Saint-Pierre University Hospital, Brussels, Belgium, 7Frauenklinik Innenstadt, Klinikum der Universität München, München, Germany, 8Klinik für Geburtshämatologie, Charité Universitätsmedizin, Berlin, Germany, 9Imperial College Healthcare NHS Trust, London, United Kingdom

Background: Perinatal guidelines include ritonavir-boosted darunavir (DRV/r) as an alternative protease inhibitor for use in antiretroviral (ARV)-naive pregnant women. The dosing recommendation for ARV-naive patients is DRV/r 800/100mg QD but pharmacokinetic data on this dose in pregnant women are limited.

Methodology: Patients treated with DRV/r (800/100mg QD) during pregnancy had intensive steady-state 24-hour PK profiles in the 3rd trimester and at least 2 weeks postpartum. Geometric mean ratios (GMR) and 90% confidence intervals (CI) were calculated for PK parameters 3rd trimester/postpartum. Unbound concentrations were determined using an ultracentrifugation method.

Results: 15 patients were included in the analysis, 11 were treatment experienced at conception. 7 patients were Black and 8 Caucasian. Seven paired PK curves (3rd trimester and postpartum) were available. Median gestational age at delivery was 38 (36-41) weeks. Approaching delivery 73% had an HIV viral load <50 cps/mL, 93% <1000 cps/mL. Two weeks prior to delivery one patient still had a significant viraemia: (28,711 copies/mL). This patient was thought to be non-adherent and had directly observed therapy until delivery. All children were born uninfected. No congenital abnormalities were reported. GMR (90% CI) of DRV PK parameters 3rd trimester/postpartum were: 0.63 (0.51-0.77) for AUC; 0.72 (0.57-0.93) for Cmax; 0.36 (0.22-0.58) for C24h. Mean free fraction (95%CI) was 12% (11-14%) in the 3rd trimester and 10% (7-13%) postpartum. 2/15 of the patients showed DRV concentrations <0.55 mg/L (EC50 for resistant virus) in the 3rd trimester, versus 7% postpartum.

Conclusions: DRV/r 800/100mg QD is suggested to be the preferred dose during pregnancy for treatment experienced patients. This decrease seems not to be compensated by a higher free fraction during pregnancy. DRV/r 600/100mg BID is suggested to be the preferred dose during pregnancy for treatment experienced patients.

888 Pharmacogenetics of Efavirenz Excretion Into Human Breast Milk and Transfer To Breastfed Infants
Adeniyi Ogunjimi1,2, Marco Siccardi1, Oguchi Okara3, Oluseye Bolaj1, Saye Khoo2, Andrew Owen2

1University of Liverpool, Liverpool, United Kingdom, 2Obafemi Awolowo University, Ille-Ife, Nigeria, 3Bishop Murray Medical Centre, Makurdi, Nigeria

Background: The influence of drug metabolizing enzyme, transporter and nuclear receptor single nucleotide polymorphisms (SNPs) on efavirenz (EFV) concentrations in human breast milk and infants exposed through breast milk is understudied. SNPs in maternal CYP2B6, NR1I3, ABCG2 and ABCB5 were investigated here.

Methodology: HIV positive nursing mothers (n = 51) receiving once daily regimens containing 600 mg EFV and their exclusively breastfed infants were recruited from 3 Nigerian hospitals. Paired dried blood spots (DBS; maternal and infant) and dried breast milk spots (DMS) were collected 12 - 14 hours post maternal dose. EFV was quantified by validated LC-MS/MS. Plasma EFV concentration was estimated using [DBS[EFV]/(1-HCTf)]*fbpp, where HCT is average haematocrit and fbpp is fraction bound to plasma protein. Genotyping for CYP2B6 rs3745274, NR1I3 rs2307424, NR1I3 rs3003596, ABCB5 rs6461515, ABCB5 rs2301641, ABCG2 rs2231164 and ABCG2 rs2622604 was conducted. Associations of EFV concentrations with SNPs and demographic factors were investigated by univariate (Mann-Whitney U test) and multivariate analyses (multiple linear regression). P < 0.05 was considered statistically significant.
Results: Median (IQR) EFV breast milk concentration was 2280 (1180, 3270) ng/ml. Using 150ml/kg/day as average milk intake, this equates to a ~340 (177, 491) μg/kg/day infant dose and resulted in 178 (87.7, 340) ng/ml in infant plasma. Maternal plasma EFV was 2310 (1580, 4460) ng/ml and median (IQR) milk-to-maternal plasma ratio was 0.82 (0.51, 1.1). There were significant correlations between maternal plasma and breast milk EFV concentrations ($p = 1.3 \times 10^{-12}$; $r = 0.80$) and between breast milk and infant plasma ($p = 7.9 \times 10^{-5}$; $r = 0.52$). Significant differences in maternal, infant and breast milk EFV concentrations were observed based on CYP2B6 rs3745274 genotypes (Figure). Only CYP2B6 rs3745274 was independently associated with breast milk $[\beta = 0.22 (0.10, 0.35), p = 0.001]$, maternal $[\beta = 0.23 (95\% CI: 0.13, 0.32), p=1.5 \times 10^{-5}]$ and infant $[\beta = 0.23 (0.09, 0.37), p = 0.002]$ EFV concentrations in multivariate analyses. Other statistically significant SNP associations were observed in univariate but not multivariate analysis.

Conclusions: CYP2B6 rs3745274 was independently associated with EFV concentrations in human breast milk and infants exposed through breast milk. Further study is warranted to define clinical significance and implications for stratified medicine in these patients.
890  A Comparison of the Pharmacokinetics of Raltegravir During Pregnancy and Postpartum  
Maren Blonk1, Angela Colbers1, Carmen Hidalgo-Tenorio2, Katharina Weizsäcker3, José Moito4, David Hawkins5, Marchina van der Ende6, Andrea Gingelmaier7, Graham Taylor8, David Burger9, PANNA Network  
1Department of Pharmacy, Radboud University Medical Center, Nijmegen, Netherlands, 2Hospital Universitario Virgen de las Nieves Granada, Granada, Spain, 3Klinik für Geburtsmedizin, Charité Universitätsmedizin, Berlin, Germany, 4Lluita contra la Sida Foundation, Hospital Universitari Germans Trias i Pujol, Badalona, Spain, 5Chelsea & Westminster Hospital, London, United Kingdom, 6Enschedes Medisch Centrum, Rotterdam, Netherlands, 7Fraunhofer Klinikum Innenstadt, Klinikum der Universität München, München, Germany, 8Imperial College Healthcare NHS Trust, London, United Kingdom  

Background: During pregnancy physiological changes take place which can influence the pharmacokinetics (PK) of antiretroviral agents and lead to decreased drug exposure. Effective plasma concentrations are important to prevent treatment failure, development of resistance and mother-to-child transmission. According to perinatal guidelines raltegravir (RAL) can be used in pregnant HIV infected women in special circumstances, because safety and PK information is limited. The use of RAL in late pregnancy for women who have a high viral load (VL) has been suggested because of its ability to rapidly suppress VL. More data on the PK behaviour and safety of RAL during pregnancy are needed to be able to recommend its use in this setting.  

Methodology: An open-label, multi-centre phase IV study in HIV infected pregnant women recruited in HIV treatment centers in Europe (PANNA Network). Patients treated with RAL 400 mg BID during pregnancy had intensive steady-state 12-hour PK profiles in the 3rd trimester and at least 2 weeks postpartum. Where possible a cord blood (CB) and matching maternal blood samples were taken at delivery to assess placental transfer. Safety and virological efficacy were evaluated.  

Results: Fourteen patients (8 Black, 6 Caucasian) were included in the analysis of which 5 patients were treatment naive at conception. Paired PK curves (3rd trimester and postpartum) were available for 12 and 3rd trimester only for two patients. Treatment with RAL was started during pregnancy in 11/14 women, of which 5 were in the 3rd trimester. RAL was combined with a PI-based regimen in 9/14 patients. Median (range) gestational age at delivery was 38 weeks (36-41); birth weight was 3115 (2300-3730) gm. Approaching delivery 10/14 patients had a VL <50 cps/mL, all were <1,000 cps/mL. No SAEs were reported. None of the children were HIV infected and no birth defects were reported. Geometric mean ratios (90% CI) of RAL PK parameters 3rd trimester/postpartum were: 0.77 (0.59-1.00) for AUC0-12h; 0.83 (0.55-1.25) for Cmax; 0.54 (0.28-1.05) for C12h. Geometric mean (95% CI) for AUC0-12h, Cmax and C12h in the 3rd trimester were: 4.95 (3.01-8.13) mg*h/L, 1.40 (0.74-2.65) mg/L and 0.054 mg/L (0.032-0.091) mg/L respectively. One patient in the 3rd trimester (and none postpartum) had a C12h level below the suggested threshold of 0.020 mg/L which was associated with failure to achieve an undetectable VL in QDMRK. The median (range) ratio of CB/maternal RAL concentrations (n=8), was 1.24 (0.13-4.53).  

Conclusions: The slight decrease observed in exposure to RAL during 3rd trimester compared to postpartum is not considered to be of clinical importance. RAL was well tolerated during pregnancy without causing congenital abnormalities. RAL efficiently crosses the placenta.  

891  Intensive Etravirine PK and HIV-1 Viral Load in Breast Milk and Plasma in HIV+ Women Receiving HAART  
LaShonda Y. Spencer1, Siyu Liu2, Chia-Hao Wang3, Michael Neely4, Stan Louie5, Andrea Kovacs6  
1Pediatric Infectious Diseases, Keck School of Medicine at University of Southern California, Los Angeles, CA, United States, 2University of Southern California School of Pharmacy, Los Angeles, CA, United States  

Background: MTCT of HIV can occur at different time periods perinatally: in utero, at time of delivery or during breast feeding. Breast feeding accounts for 6.5%-25.9% of infections worldwide, with the majority of transmissions occurring in the first 6 weeks of life. ARVs with good penetration into breast milk (BM) have the greatest impact on decreasing MTCT transmission through breastfeeding.  

Methodology: Nine HIV+ postpartum women on stable HAART with an undetectable viral load added Etravirine (ETR) to their current regimen on postpartum Day 1 and continued for 14 days. Intensive PK sampling of BM and plasma was done on postpartum days 5 (D5) and 14 (D14) at times 0, 2, 5 and 24 hours after the dose of ETR. BM and plasma HIV-1 RNA viral load (VL) were quantified. ETR drug concentrations were measured by a validated LC/MS/MS assay. Non-compartmental analysis was used to estimate PK parameters.  

Results: The median BM concentration of ETR on D5 was 241.46 ng/ml (160.76-890.8) and on D14 was 797.77 ng/ml (161.02-2714.2) p=0.046. The median plasma concentrations were 299.9 ng/ml (52.76-563.8) and 196.9 ng/ml (131.88-706.4) on D5 and D14 respectively. The median BM:plasma ratio on D5 and D14 was 1.09 ng/ml (0.59-3.04) on D5 and 3.27 ng/ml (1.25-4.55) P=0.01. BM concentrations exceeded the upper limit of the ETR IC 50 range (0.39-2.4 ng/ml) in all patients. HIV RNA levels were detectable in the BM of two patients despite undetectable plasma HIV RNA. ETR AUC0-12h and BM:plasma ratios did not differ in the detectable vs. the undetectable women.  

Conclusions: ETR penetration into BM is largely driven by plasma PK and exceeds the plasma HIV inhibitory concentration at all time points. This study suggests that unbound ETR readily diffuses from blood to the breast compartment likely because of its lipophilicity. However, differences in concomitant ARVs and individual pharmacodynamics may allow for compartmental viral replication. HAART combinations that include ETR may prove useful for prevention of BM MTCT in resource limited countries where exclusive breastfeeding is recommended.  

892  Effective Exposure To Atazanavir During Pregnancy, Regardless of Tenofovir Use  
Angela Colbers1, David Hawkins2, Carmen Hidalgo-Tenorio3, Marchina van der Ende4, Kabamba Kabeya5, Andrea Gingelmaier6, Katharina Weizsäcker7, John Lambert8, Jürgen Rockstroh9, David Burger10  
1Department of Pharmacy, Radboud University Medical Center, Nijmegen, Netherlands, 2Chelsea & Westminster Hospital, London, United Kingdom, 3Hospital Universitario Virgen de las Nieves Granada, Granada, Spain, 4Erasmus Medical Center, Rotterdam, Netherlands, 5Saint-Pierre University Hospital, Brussels, Belgium, 6Fraunhofer Klinikum Innenstadt, Klinikum der Universität München, München, Germany, 7Klinik für Geburtshilfe, Charité Universitätsmedizin, Berlin, Germany, 8Mater and Rotunda Hospitals, Dublin, Ireland, 9Department of Medicine I, University of Bonn, Bonn, Germany, 10Department of Pharmacy, Radboud University Medical Center, Nijmegen, Netherlands  

Background: Atazanavir with low-dose ritonavir boosting moved from an alternative protease inhibitor to a preferred protease inhibitor for use in antiretroviral-naïve pregnant women. The package insert recommends an atazanavir (ATV) dose increase in the 2nd and 3rd trimester of pregnancy if
tenofovir (TDF) or an H2 receptor antagonist is used concomitantly. Conflicting data exist about the influence of TDF on ATV concentrations, and therefore also for the necessity to increase the ATV dose in the 2nd and 3rd trimester of pregnancy if used with TDF.

Methodology: Patients treated with ATV/r (300/100mg QD) during pregnancy had intensive steady-state 24-hour PK profiles in the 3rd trimester and at least 2 weeks postpartum. Geometric mean ratios (GMR) and 90% confidence intervals (CI) were calculated for PK parameters 3rd trimester/postpartum. PK parameters with and without TDF co-treatment were compared by an independent t-test.

Results: 29 patients were included in the analysis, 11 were treatment naive at conception. 15 patients were black and 14 Caucasian. Paired PK curves (3rd trimester and postpartum) were available for 25 patients. 19/29 patients used TDF as part of the combination antiretroviral therapy.

Median gestational age at delivery was 39 (36-42) weeks. Approaching delivery 76% had an HIV viral load <50 cps/mL, all <1000 cps/mL. GMR (90% CI) of ATV PK parameters 3rd trimester/postpartum were: 0.65 (0.56-0.74) for AUC; 0.69 (0.60-0.79) for C max; 0.58 (0.47-0.71) for C24h. No statistical difference in AUC was found between patients using TDF vs no TDF: GM (95%CI) 3rd trimester 28.9 mg*h/L (22.2-37.4) vs 32.1 mg*h/L (21.1-48.7); postpartum 46.1 (36.2-58.7) vs 49.2 mg*h/L (34.7-69.8). None of the patients showed ATV concentrations <0.15 mg/L (target for treatment naive patients). One baby had a congenital diaphragmatic hernia resulting in respiratory failure, septic shock and death. A relationship with ATV/r is not likely, because ATV/r was started in week 21 of pregnancy, whereas the closure of the pleuroperitoneal canal occurs around week 8 of pregnancy. None of the children were HIV infected.

Conclusions: Despite 35% lower ATV exposure during pregnancy, 300/100mg ATV/r seems to generate effective concentrations for PI naive patients, even if co-administered with TDF. For experienced patients therapeutic drug monitoring of ATV should be considered to adapt the ATV/r dose on an individual basis.

ART in Children and Adolescents

P1073: Immune Reconstitution Inflammatory Syndrome - Wide Spectrum and Severity in Children

Mark F. Cotton1, Hilda Mujuru2, Raziya Bobat3, Boniface Njau4, Avis Violari5, Vidya Mave6, Charles Mitchell7, James Oleske8, Bonnie Zimmer9, Savita Pahwa10

1Pediatrics & Child Health, Stellenbosch University, Tygerberg, South Africa, 2Pediatrics & Child Health, UZ College of Health Sciences, Harare, Zimbabwe, 3Pediatrics & Child Health, University of Natal, Durban, South Africa, 4Kilimanjaro Christian Medical Centre, Moshi, Tanzania, United Republic of, 5Pediatrics & Child Health, Perinatal HIV Research Unit, Tygerberg, South Africa, 6BJ Medical College, Pune, India, 7Pediatric Immunology, University of Miami, Miami, FL, United States, 8Pediatrics & Child Health, New Jersey Medical School, Newark, NJ, United States, 9Frontier Science & Technology Research Foundation, Amherst, NY, United States, 10Pediatrics & Child Health, University of Miami Miller School of Medicine, Miami, FL, United States

Background: The Immune Reconstitution Inflammatory Syndrome (IRIS) is well described after initiating antiretroviral therapy (ART) in severely immunocompromised patients. It is classified as “paradoxical” when symptoms or signs of a known co-morbidity increase or re-appear and “unmasking” with recognition of a previously unsuspected condition.

There are few prospective studies of IRIS in children.

Methodology: P1073 was a prospective multi-center observational study of children below 6 years of age initiating ART from 5 sites in sub-Saharan Africa and one in India. Children were recruited from public ART programs.

Results: 203 children (median age 1.14y; IQR 0.48 to 2.12) were enrolled from December 2010 through June 2013. Of 9 deaths (case fatality 4.4%), 6 occurred within 12 weeks of ART initiation. Of these, 3 had IRIS: 1) vasculitis and pneumonia in a child with disseminated TB, 2) esophageal candidiasis and 3) Bacille Calmette Guerin (BCG) IRIS in a child who later died of gastroenteritis.

Thirty-eight children (18.7%) developed 46 episodes of IRIS, 6 had 2 types of IRIS and 1 had 3 discrete IRIS episodes. Case fatality rate in IRIS cases was 7.9%. BCG IRIS was most common (21/46 - 45.6%); 33% only having increased inflammation at the injection site, the remainder having regional adenopathy. 11 children had TB IRIS (23.9%) and 10 had dermatological IRIS (papular pruritic eruption - 4, dermatitis - 2, molluscum contagiosum - 1, tinea capitis - 1, TB vasculitis - 1 and zoster- 1). Median time to IRIS was 3.4 (2 to 8) weeks. The earliest was on day 8 and the latest at 13.9 weeks. Those with IRIS were younger (median 0.7y vs 1.25y; p = 0.024) with lower CD4%(16.7% vs 20%; p = 0.017). Both unmasking and paradoxical IRIS had severe, unexpected morbidity. Two with CMV colitis (1 unmasking and 1 paradoxical) required ICU admission; a child with newly diagnosed pulmonary TB developed prolonged seizures due to unsuspected intra-cerebral TB granulomas. Another, with unsuspected intracerebral granulomas developed focal seizures and raised intracranial pressure requiring ICU (unmasking IRIS; treated for TB). Unmasking candida esophagitis was associated with death in 1 child and unmasking TB IRIS due to unsuspected abdominal TB led to bilary obstruction, surgery and hospitalization for 5 months in another.

Conclusions: Although many cases of IRIS were benign, some were unexpectedly severe (especially the unmasking type) with morbidity and mortality. Children initiating ART in public programs require careful monitoring for IRIS in the initial 3 months of ART.
sdNVP Exposure and ART Response in Children <3 Years Initiating ART in the ARROW Trial
Philippa Musoke1, Victor Musilme1, Kusum Natho1, Patricia Nahirya-Ntege1, Alexander J. Szubert1, Kuda Mutasai2, David E. Williams2, Moira Spyer1, Ann Sarah Walker1, Diana M. Gibb3, and the ARROW Trial Team
1Baylor-Uganda, Kampala, Uganda, 2Joint Clinical Research Center, Kampala, Uganda, *University of Zimbabwe, Harare, Zimbabwe, *MRC/UVRI Uganda Research Unit on AIDS, Entebbe, Uganda, *MRC Clinical Trials Unit, London, United Kingdom, *Zvitambo Institute for Maternal Child Health Research, Harare, Zimbabwe

Background: Poorer virologic response to NNRTI-containing regimens has been reported in children with prior sdNVP exposure. Despite WHO guidelines now recommending all children <5 years initiate LPV-containing ART, availability is limited and formulations challenging. We therefore compared VL response in children initiating ART aged <3 years in the ARROW trial according to previous sdNVP exposure.

Methodology: In 2007-2008, 370 ART-naïve children aged <3 years were enrolled from Uganda/Zimbabwe, and randomized to standard 3-drug NNRTI+3TC+ABC (Arm A) vs 4-drug NNRTI+3TC+ABC+ZDV induction, decreasing at 36 weeks to 3-drug NNRTI+3TC+ABC (Arm B) or to 3TC+ABC+ZDV (Arm C). VL was assayed using Abbott Taqman or Roche Amplicor, with lower detection limit 80 c/ml. Predictors of suppression <80 c/ml 48 and 144 weeks after ART initiation were identified using backwards elimination (p=0.1) from pre-ART CD4%, weight/height-for-age, CD4%, VL, sex, centre, ART randomisation, CD4 monitoring (yes/no), current ART as all syrups, and reported missed ART doses in the last 4 weeks, forcing sdNVP and age at ART initiation into the model.

Results: Three children initiated ART with EFV and were excluded. In the remaining 367 initiating NVP-based ART aged <3 years, median age was 20 months (IQR 12-27). 57 (16%) children had received sdNVP. Children receiving sdNVP were younger (median 15 vs 20 months in those without sdNVP, p=0.003) and therefore had slightly higher CD4 counts (median 902 vs 724 cells/ul, p=0.02) and lower weight (median 7.8 vs 8.4 kg, p=0.05), but did not differ significantly in pre-ART CD4% (median 14%), VL (508314 c/ml), weight-for-age Z-score (-2.7) WHO stage (71% 3/4), sex (48% boys), centre/country or initial ART (p>0.15). There was no evidence that suppression <80 c/ml was any worse with sdNVP vs no sdNVP exposure (Figure; wk48 adjusted (a)OR=1.84 [95% CI 0.83-4.05] p=0.13, wk144 aOR=1.39 [0.66-2.95] p=0.38). At week 48/144, suppression was lower in boys (aOR=0.45/0.56 p=0.004/0.03) and those without pre-ART CD4% (median 14%), VL (508314 c/ml), weight-for-age Z-score (-2.7) WHO stage (71% 3/4), sex (48% boys), centre/country or initial ART (p=0.15/0.04). There was no independent effect of age (p=0.42/0.14).

Conclusions: In this cohort of African children <3 years of age starting ART with advanced HIV disease, there was no evidence of poorer VL response to NVP-containing ART in children exposed to sdNVP.

Virologic Response To Efavirenz vs Nevirapine-Containing ART in the ARROW Trial
Adeodata Kekitiinwa1, Moira Spyer2, Richard Katuramu1, Victor Musilme1, Tawanda Mhute3, Sabrina Kitaka1, Oscar Senfuma4, Marshall Munjoma5, Ann Sarah Walker2, Diana M. Gibb3, and the ARROW Trial Team
1Baylor-Uganda, Kampala, Uganda, 2MRC Clinical Trials Unit, London, United Kingdom, 3MRC/UVRI Uganda Research Unit on AIDS, Entebbe, Uganda, 4Joint Clinical Research Center, Kampala, Uganda, 5University of Zimbabwe, Harare, Zimbabwe

Background: Poorer virologic response to NVP vs EFV-based ART has recently been reported. We compared VL response in ARROW trial children aged ≥3 years initiating ART with NVP vs EFV.

Methodology: 836 ART-naïve children age ≥3 years from Uganda/Zimbabwe were randomized to 3-drug NNRTI+3TC+ABC (Arm A) vs 4-drug NNRTI+3TC+ABC+ZDV induction, decreasing at week 36 to 3-drug NNRTI+3TC+ABC (Arm B) or 3TC+ABC+ZDV (Arm C). NNRTI was chosen by clinicians. VL was assayed using Abbott Taqman or Roche Amplicor, with lower detection limit 80 c/ml. Predictors of suppression <80 c/ml at 36wk (all children) and 144wk (Arm A/B only) after ART initiation were identified using backwards elimination (p=0.1) from pre-ART CD4%, weight/height-for-age, CD4%, VL, sex, centre, ART randomisation, CD4 monitoring (yes/no), current ART as all syrups, and reported missed ART doses in the last 4wk, forcing EFV vs NVP and age at ART initiation into the model, and categorizing age to reflect non-linear effects.

Results: 445 (53%) children received EFV and 391 (47%) NVP. Children on EFV were more likely to be male (58%, p=0.007), older (median 8.6 year EFV vs 7.5 NVP, p<0.001), less underweight (weight-for-age -1.7 vs -2.4, p<0.001) and had higher CD4% (12% vs 10%, p=0.05) and lower pre-ART VL (160011 vs 203888c/ml, p=0.07), but similar pre-ART CD4 (p=0.9). 631 (75%) had ≥1 post-baseline VL. Overall there was a trend to better suppression <80 c/ml with EFV (Figure; global unadjusted p=0.08, particularly ≤36wk). After adjustment, at wk 36 (n=274 to date), EFV was superior to NVP in
those with pre-ART VL > 75000 (p = 0.001; interaction p = 0.003); suppression < 80 c/ml was poorer in the youngest and oldest children (aOR (3-4 vs 5-9yr olds) = 0.57 p = 0.14; aOR (10+ vs 5-9yr olds) = 0.33 p = 0.007). Differences at wk144 were smaller (75% EFV vs 70% NVP < 80 c/ml (n=196)) but still significant (p = 0.03), with a strong relationship between older age and poorer VL suppression in those on EFV (aOR per year older = 0.78 [0.68-0.89] p < 0.001) but no relationship in NVP (aOR = 0.97 [0.80-1.17] p = 0.74) (age interaction p = 0.06).

Conclusions: In a non-randomized NNRTI comparison, although short-term VL suppression favoured EFV, long-term suppression depended on age: children < 10 years at ART initiation had better long-term VL suppression with EFV than NVP; whereas those > 10 years had better long-term suppression with NVP than EFV. The relative performance of EFV vs NVP therefore varies over time on ART, by baseline VL and by age at ART initiation, the latter possibly due to CNS side-effects of EFV.

986 Growth Recovery Among HIV+ Children Randomized To Lopinavir/Ritonavir or NNRTI-Based Therapy

Theodore Ruel1, Abel Kakuru2, Gloria Ikole2, Florence Mwangwa2, Albert Plenty3, Edwin Charlebois4, Diane Havlir5, Moses Kamya6, Jane Achan5

1Department of Pediatrics, Division of Infectious Diseases, University of California San Francisco, San Francisco, CA, United States, 2Infectious Diseases Research Collaboration, Kampala, Uganda, 3Department of Medicine, University of California San Francisco, San Francisco, CA, United States, 4Infectious Diseases Research Collaboration, Kampala, Uganda, 5Department of Medicine, Makerere University College of Health Sciences, Kampala, Uganda

Background: HIV-infected African children suffer high rates of wasting and short stature. Growth generally improves with the initiation of antiretroviral therapy (ART), but some studies have suggested poorer outcomes with the use of lopinavir/ritonavir (LPV/r). We compared the recovery of weight and height in a rural cohort of HIV-infected children randomized to initiate LPV/r- or non-nucleoside-reverse-transcription-inhibitor (NNRTI)-based ART.

Methodology: In the PROMOTE-pediatrics trial, HIV-infected children aged 2 months to 6 years were enrolled in Tororo, Uganda, and randomized to NNRTI- or LPV/r-based ART. Children were seen monthly and received food supplementation if malnourished. This analysis included data from the 24 months following ART-initiation among ART-naïve enrollees on a per-protocol basis. Changes in gender specific World Health Organization Z-scores for weight-for-age (WAZ) and height-for-age (HAZ) compared to enrollment were compared by arm using generalized linear repeated-measure models that adjusted for baseline Z-score score, socioeconomic status and confirmed virologic failure (consecutive HIV RNA > 400 copies/ml).

Results: At enrollment, 129 children had median (IQR) age of 3.2 years (2.2, 4.5), CD4 count of 588 cells/mm3 (389, 913), CD4 percentage of 16 (12, 23), HIV RNA level of 5.4 log10(copies/ml) (4.8, 5.9), WAZ of -1.3 (-2.4, -0.61) and HAZ of -2.38 (-3.28, -1.41). Median (IQR) follow-up times were 23.9 months (18.4, 23.9) for the LPV/r arm (n=64) and 23.8 months (17.5, 23.9) for the NNRTI arm (Nevirapine: n=36, Efavirenz: n=29). The height and weight of HIV-infected Ugandan children in both arms improved steadily over 24 months following ART-initiation (figure). The median (IQR) change in Z-scores among children who reached 24 months of follow-up on LPV/r (n = 45) vs NNRTI (n = 40) were, respectively, WAZ: 0.47 (0.10, 1.62) vs 0.53 (0.03, 1.14) (p = 0.59) and HAZ: median 1.55 (0.78, 1.86) vs 1.19 (0.62, 1.65) (p = 0.23). In multivariate modeling, study arm (LPV/r vs. NNRTI) was not predictive of change in WAZ (beta: 0.02, 95% CI: -0.25, 0.20) or HAZ (beta: 0.05, 95% CI: -0.10, 0.19).

Conclusions: Our results suggest that as the use of LPV/r expands throughout Africa, HIV-infected children receiving LPV/r in similar settings can be expected to have comparable growth to children receiving NNRTI-based ART. However, that Z-scores remained below zero underscores the need for additional strategies to improve growth in HIV-infected African children.
Prevalence and Predictors of HIV Drug Resistance Among US Children and Youth With Perinatal HIV

Russell B. Van Dyke1, Kunjal Patel2, Ron M. Kagan3, Shirley Traite4, William A. Meyer5, Katherine Tassiooulos6, George R. Seage2, Lorna M. Seybolt7, Sandra Burchette7, Rohan Hazra8, and the Pediatric HIV/AIDS Cohort Study

1Department of Pediatrics, Tulane University School of Medicine, New Orleans, LA, United States; 2Department of Epidemiology, Harvard School of Public Health, Boston, MA, United States; 3Quest Diagnostics Nichols Institute, San Juan Capistrano, CA, United States; 4Center for Biostatistics in AIDS Research, Harvard School of Public Health, Boston, MA, United States; 5Department of Pediatrics, Baltimore, MD, United States; 6Department of Pediatrics, Louisiana State University Health Sciences Center, New Orleans, LA, United States; 7Department of Pediatrics, Harvard Medical School, Boston, MA, United States; 8Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, MD, United States

Background: With extensive antiretroviral (ARV) exposure and the challenge of maintaining adherence, children and youth with perinatal HIV are at high risk for acquired drug resistance.

Methodology: The Adolescent Master Protocol of the Pediatric HIV/AIDS Cohort Study is a prospective study being conducted at 14 U.S. sites. From 2007 to 2009, we enrolled 451 subjects with perinatal HIV who were 7-16 years of age at entry. We abstracted results from genotypic resistance testing performed for clinical care. For subjects without these results and with a viral load (VL) ≥400 copies/mL, their most recent plasma sample was sent for genotypic resistance testing at a reference laboratory (Quest Diagnostics). Results were compared to the overall results from the reference laboratory for 2006 and 2012. Correlates of resistance were assessed using the Wilcoxon Test for continuous and Chi-square Test for categorical variables.

Results: Of the 446 subjects with at least one VL performed on study, 284 (64%) had at least one VL ≥400 copies/mL and 230 had resistance testing results from 2007-2013 (median 2010). Their median age at testing was 14.8 years; 57% were female, 70% black and 25% Hispanic. 74% had any ARV resistance; 61%, 40%, and 34%, respectively, had resistance to any NRTI, any NNRTI, or any PI. Differences in prevalence of resistance for the reference laboratory population (Table). The prevalence of resistance was highest for: zidovudine, nevirapine, and efavirenz (40%); stavudine (39%); lamivudine (37%); and didanosine and nelfinavir (32%). The prevalence of resistance was lowest for lopinavir (18%), etravirine (15%), tipranavir (10%), and darunavir (4%). Resistance to all ARVs in a class was uncommon (Table). Univariable correlates of resistance included more cumulative years of HAART (p=0.03), a lower pre-HAART nadir CD4% (p=0.005), a higher pre-HAART peak VL (p<0.001), and a lower current VL (p=0.02). Factors not significantly associated with resistance included use of ART prior to HAART, current CD4 count, current CDC class, and current ARV adherence. At their most recent visit, 67% of AMP subjects had a VL < 400 copies/mL.

Conclusions: Viral resistance is common among U.S. youth with perinatal HIV, including resistance to multiple ARV classes, with a prevalence of resistance substantially higher than that of the general U.S. HIV-infected population. Resistance to newer ARVs is less common and effective higher than that of the general U.S. HIV-infected population.

HIV-1 Resistance After Randomized Virologic Switch at 1000 or 3000 c/ml in Children

Linda Harrison1, Diana Gibb2, Susan Fiscus3, Yacine Saidi4, Eleni Nastouli5, Lynda Harper5, Alexandra Compagnucci6, Abdel Babiker7, Ann Melvin8, Gareth Tudor-Williams9, and the PENPACT 1 (PENTA 9/PACTG 390) Study Team

1Center for Biostatistics in AIDS Research, Harvard School of Public Health, Boston, MA, United States; 2Medical Research Council, Clinical Trials Unit, London, United Kingdom; 3UNC-Chapel Hill Virology Laboratory, University of North Carolina School of Medicine, Chapel Hill, NC, United States; 4INSERM, SC10, Paris, France; 5University College Hospital, University College London, London, United Kingdom; 6Seattle Children’s Hospital, Seattle, WA, United States; 7Department of Pediatrics, University College London, London, United Kingdom; 8Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, MD, United States

Background: There are no comparisons of resistance after randomized virologic switch criteria.

Methodology: PENPACT 1 was an international open label 2 by 2 factorial trial randomizing HIV infected children to start antiretrovirals with a protease inhibitor (PI) vs non nucleoside reverse transcriptase inhibitor (NNRTI) based regimen, and switch at RNA threshold of 1000 vs 30000 c/ml. Switch criteria were: not achieving the threshold by week 24, confirmed rebound above the threshold after week 24 (RNA tested 12 weekly), or CDC C event. Resistance testing was on samples ≥1000 c/ml at 4 years and trial end. This secondary analysis tested differences in number of major IAS mutations by Poisson models.

Results: Of 263 children, 67 started PIs and were assigned the 1000 threshold (PI 1000), 64 PI 30000, 67 NNRTI 1000 and 65 NNRTI 30000. Half on PIs started lopinavir/ritonavir, 62% on NNRTIs efavirenz (Table). The 1000 criteria were reached by 94 (36%) children during median 5.0 (IQR 4.2-6.0)
years follow-up. Time to reaching the 1000 criteria was similar by class (log rank P 0.26). Most in the 1000 arm reaching the criteria switched soon after (PI vs NNRTI median 12 vs 8 wks, log rank P 0.60). Median weeks from 1000 to 30000 criteria was 80 for the 30000 arm; PI vs NNRTI 58 vs 80, log rank P 0.81, and 25% of children had switched by 44 weeks; PI vs NNRTI 63 vs 17, log rank P 0.16. 87/107 (81%) children with last sample ≥1000 c/ml had resistance test results. Median weeks from entry to last test was 96; 1000 vs 30000 72 vs 124, rank sum P<0.01. More NRTI resistance mutations were accumulated in NNRTI 30000 than the other arms (Table). More NNRTI than PI mutations were accumulated; NNRTI mutations were frequent in 1000 and 30000, and PI resistance was less common in both arms. For non-randomized NRTIs, 62 started ABC+3TC, 166 3TC+ZDV/d4T, and 35 other (25 ZDV+ddI). The ABC+3TC group had fewer mutations than the others. The 5 with mutations on ABC+3TC were on NNRTIs; all had M184V/I and 1 K65R, L74V, Y115F, while 22/39 3TC+ZDV/d4T were on NNRTIs; all had M184V/I and 10 had TAMs.

Conclusions: Children starting PIs tended to switch later spending longer above 1000 but accumulated fewer mutations. Children starting NNRTIs switched soon after the 30000 criteria and accumulated more mutations, particular to NRTIs. An ABC+3TC backbone seemed most protective against NRTI resistance.

899 Longitudinal Evolution of Tropism in Perinatal HIV-1 Infection: The HICCUP Study
Caroline Foster1, Steve Kaye2, Colette Smith3, Nicola Mackie4
1900 Clinic, Imperial College Healthcare NHS Trust, London, United Kingdom, 2Jefferies Trust Laboratory, Imperial College London, London, United Kingdom, 3Research Department of Infection and Population Health, University College London, London, United Kingdom, 4Jefferies Wing, Imperial College Healthcare NHS Trust, London, United Kingdom

Background: Data on changes over time in HIV tropism and association with disease progression in perinatal HIV-1 infection (PaHIV) is sparse. Optimal sequencing of antiretrovirals (ART) including CCR5 antagonists is a priority for a young population currently requiring life long ART and requires a clear understanding of the natural history of coreceptor usage in PaHIV.

Methodology: Eligible patients with PaHIV were CCR5 antagonist naïve and were defined as (1) slow (ART from 10+ yrs) or (2) rapid (ART pre 5 yrs) progressors and (3) long term non-progressors (LTNP). RNA was extracted from stored plasma samples at baseline and at yearly time points or virological
failure to latest follow up. The V3 region of gp120 was sequenced and tropism determined using the Geno2pheno algorithm (FPR 5.75%). Logistic regression with generalised estimating equations was used to assess factors associated with the presence of R5 virus. Time to tropism change was assessed using standard survival methods.

**Results:** At baseline ($n=48$) median age was 12 yrs, 52% female, 79% black African, 96% non-B subtype, group 1 ($n=20$), 2 ($n=17$) and 3 ($n=11$). 81% (39/48) had R5 and 19% (9) had X4/dual-mixed (DM) viruses. Median follow-up was 7.7 yrs (308.6 person-yrs) with a median of 5 (range 1-14) samples per subject (252 samples total). Analysing all samples, the presence of R5 virus was associated with higher current CD4 count (median 520 cells/$\mu$L for R5 virus vs 202 for X4; $p=0.0005$), LTNP (35% vs 11%; $p=0.05$), non Black African ethnicity (74% vs. 89%; $p=0.05$) and female (55% vs 28%; $p=0.005$).

Of 38 patients with R5 virus at baseline and at least one follow-up sample, switch to X4/DM occurred in 12 (30.8%). Estimated 5 yr risk of tropism switch to X4/DM was 24.4% (95% CI 9.7-39.2%). Lower current CD4 predicted coreceptor switch (unadjusted HR=0.62 per 50 cells higher; 95% CI 0.47-0.81; $p=0.0006$) but not viral load ($p=0.81$), age ($p=0.85$) or clinical group ($p=0.56$). Of 19 patients who ever had X4/DM virus and at least one further sample, 11 (58%) had R5 virus at one or more subsequent time points. 5/11 had three or more switches between R5 and X4/DM over time, 3 of whom were R5 at last follow up.

**Conclusions:** As seen in adult studies, lower CD4 count was predictive of coreceptor switching in PaHIV. CCR5 antagonists were a treatment option for 81% at 12 yrs, falling to 56% over 7.7 yrs of follow up. Globally 30% of children with PaHIV are triple class experienced and currently are expected to remain on ART for life. Paediatric studies of CCR5 antagonists should be expedited to ensure they are a treatment option before tropism switching occurs in children. The frequent reversion from X4 to R5 may result in CCR5 antagonists being prescribed to patients harbouring undetected X4 virus and careful monitoring of individuals commencing such therapy is indicated.

**900 Rilpivirine Pharmacokinetics in HIV-1-Infected Adolescents: A Substudy of PAINT (Phase II Trial)**

Herta Crauwels1, Annemie Hoogstede2, Simon Vaneggele1, Wayne Yarnall1, Marita Stevens1, Kalia Boven1

1Janssen Infectious Diseases BVBA, Beerse, Belgium, 2Janssen Research & Development, LLC, Titusville, NJ, United States

**Background:** Rilpivirine (RPV) is a non-nucleoside reverse transcriptase inhibitor (NNRTI) approved in combination with other antiretrovirals for the treatment of HIV-1-infected, treatment-naive adults. RPV pediatric dosing has not been established. PAINT (Pediatric study in Adolescents Investigating a New NNRTI TMC278, NCT00799864) is an ongoing, open label, 48-week Phase II trial to evaluate RPV pharmacokinetics (PK), safety/tolerability and antiviral activity in adolescents. Part 1 of PAINT aimed to establish, in a subset of adolescents, a well-tolerated RPV dose providing comparable exposure to adults. Steady-state PK data from Part 1 are presented.

**Methodology:** Antiretroviral treatment-naive HIV-1-infected adolescents (>12–≤18y) were recruited from investigational sites (India, Thailand, Uganda, South Africa). All patients were treated with RPV 25mg once daily (qd), taken with a meal, and two nucleoside/nucleotide reverse transcriptase inhibitors. A steady-state 24h PK profile was determined using blood samples collected predose, 2, 4, 5, 6, 9, 12 and 24h after an observed RPV dose, at the Week 2 or Week 4 visit. RPV plasma concentrations were determined by liquid chromatography-tandem mass spectrometry (1.0 ng/mL lower limit of quantification), and RPV PK parameters with non-compartmental analyses.

**Results:** Twenty-five adolescents were enrolled in Part 1, 12 were >12–≤15y and 13 were >15–≤18y old. There were 11 males and 14 females; 4 were Asian and 21 Black. Intensive PK data were available for 23 adolescents. The geometric mean (SD) AUC24h, C0h and Cmax were 1715 (718) ng•h/mL, 70.6 (40.4) ng/mL and 102 (38.0) ng/mL, respectively. These values are comparable to those observed in adult HIV-1-infected patients. Geometric mean PK parameter ratios (adolescents/adults) were 0.98, 1.21 and 0.88 for AUC24h, C0h and Cmax, respectively. There was no apparent relationship between RPV PK parameters and bodyweight, and no apparent difference in RPV PK parameters between age categories or between genders. At Week 4, the mean (SE) observed decrease from baseline in viral load was 2.3 (0.17) log10 copies/mL, and the mean (SE) observed increase in CD4+ cell count was 104.6 (27.20) cells/mm3. Up to week 4, 16/25 (64%) patients experienced at least one adverse event (AE), none serious or grade 4, considered related to RPV in 8/25 (32%). The observed AEs were similar (type and severity) to those reported in adults (53% up to Week 4).

**Conclusions:** The RPV dose selected for further evaluation in adolescents >12–≤18y old is 25mg qd with a meal. This dose provides comparable RPV exposure in adolescents and adults, and was generally safe and well tolerated. Long-term safety/tolerability, antiviral activity and further PK of RPV in adolescents are being investigated in Part 2 of PAINT.

---

**901 Safety, Pharmacokinetics and Efficacy of Dolutegravir in Treatment-Experienced HIV+ Children**

Rolando M. Viani1, Carmelita Alvero1, Terry Fenton1, Edward Acosta1, Rohan Hazra1, Ellen O’Gara1, Barbara Heckman1, Debra Steimers1, Sherene Mini1, Andrew Wiznia1

1University of California San Diego, La Jolla, CA, United States, 2Harvard School of Public Health, Boston, MA, United States, 3University of Alabama at Birmingham, Birmingham, AL, United States, 4NICHD, Bethesda, MD, United States, 5NIAID, Bethesda, MD, United States, 6Frontier Science Research Foundation, Inc, Amherst, NY, United States, 7GlaxoSmithKline, Research Triangle Park, NC, United States, 8Jacobi Medical Center, Bronx, NY, United States

**Background:** IMPAACT P1093 is an ongoing Phase I/II multicenter open-label PK, safety/tolerability and antiviral efficacy study of dolutegravir (DTG) plus optimized background regimen (OBR) in children and adolescents in age defined cohorts. Adequate pharmacokinetics (PK), safety and virologic efficacy have been described in children aged 12 to 18 years, leading to the recent FDA approval. Here we report the PK, safety and virologic efficacy of DTG in children ≥6 to < 12 years old.
Methodology: HIV infected treatment experienced children ≥6 to <12 yrs on a failing antiretroviral (ARV) regimen with an HIV RNA of ≥1000 copies/mL (c/mL) were enrolled in an intensive PK stage as part of the study. DTG tablets (10, 25, 50mg) at ≈1 mg/kg once a day (based on defined weight bands) were added to a stable, failing ARV regimen, with an OBR added after intensive PK (~Day5-10). Target PK exposures were AUC_0-24 range of 37-67 μg*h/mL (primary) and C_{24} range 0.77 - 2.26 μg/mL (secondary). Safety, tolerability, CD4 cell count and HIV-1 RNA were evaluated at Week 24. Virologic success was defined as achieving an HIV-1 RNA < 400 c/mL or ≥ 1 Log₁₀ decline in HIV RNA by Week 24 based on the FDA snapshot algorithm, with an additional secondary endpoint of HIV-1 RNA <50 c/mL.

Results: Eleven children were enrolled and completed the 24 week study visit. Demographics were as follows: 64% (7/11) male, 36% (4/11) African American, 27% (3/11) Caucasian, 18% (2/11) Asian, 36% (4/11) were of Hispanic ethnicity. Mean (SD) age was 9.5 yrs (±1.8); weight was 34.9 kg (±11.9). Median (IQR) baseline CD4+ cell count and % were 645 cells/μL (325, 732) and 19% (14, 26) respectively. Median (IQR) baseline HIV-1 RNA log₁₀ was 5.0 log₁₀ c/mL (3.5, 5.3). Five subjects (≥40 kg of weight) received DTG 50 mg, 2 subjects (30-<40 kg) received DTG 35 mg and 4 subjects (<30 kg) received DTG 25 mg once daily. DTG geometric mean (CV%) AUC_0-24 and C_{24} were 50.46 (63%) μg*h/mL and 0.92 (89%) μg/mL respectively. Virologic success was achieved in 81.8 % (9/11; 95% CI: 48.2 % to 97.7%) at Week 24. Additionally, 63.6% (7/11; 95% CI: 30.8% to 89.1%) had an HIV RNA load < 50 c/mL at Week 24. Median (IQR) gain in CD4 cell count and % at Week 24 was 209 cells/μL (14, 403) and 8% (6, 11) respectively. DTG was well tolerated, with 3 subjects experiencing Grade 3 laboratory abnormalities; two developed unconjugated bilirubin elevation while on atazanavir as part of the OBR, and another subject developed neutropenia, which was deemed unrelated to treatment. There were no Grade 4 AEs, SAEs or study discontinuations due to AEs.

Conclusions: DTG plus OBR had a favorable safety profile and achieved adequate mean AUC_{24} and C_{24} in HIV infected children ≥ 6 to < 12 years. DTG plus OBR provided good virologic efficacy through Week 24 in this pediatric population.

Bioequivalence of Two Pediatric Formulations vs Adult Tablet Formulation of Elvitegravir

Joseph M. Custodio1, Xiang Yin2, Hiba Graham3, Mischa Hepner4, Lauren Wiser5, Erin Quirk3, Brian P. Kearney1, Srinivasan Ramanathan1

1Clinical Pharmacology, Gilead Sciences, Foster City, CA, United States, 2Biometrics, Gilead Sciences, Foster City, CA, United States, 3Clinical Research, Gilead Sciences, Foster City, CA, United States, 4Clinical Operations, Gilead Sciences, Foster City, CA, United States, 5Formulations Process Development, Gilead Sciences, Foster City, CA, United States

Background: Safe and effective pediatric antiretroviral therapies are needed. Elvitegravir (EVG) is a once-daily integrase inhibitor in regulatory review for treatment of HIV-1 infection when coadministered with a pharmacoenhancer. This study evaluated the pharmacokinetics (PK) of ritonavir (RTV)-boosted EVG administered as the pediatric EVG tablet or suspension formulation (test) vs the adult EVG 150 mg tablet formulation (reference).

Methodology: This was a prospective, open-label, crossover, randomized, multiple cohort study in healthy adult subjects. Cohort 1 (n=30) evaluated the single dose PK of the pediatric tablets (3 X 50 mg) vs reference. Cohort 2 (n=26) evaluated the single dose PK of the pediatric suspension (30 mL; 5 mg/mL) vs reference. Cohort 3 (n=18) evaluated the multiple dose PK of both pediatric formulations. All treatments included 100 mg of RTV as a pharmacoenhancer and were administered under fed conditions with 240 mL of water. Intensive PK sampling was conducted over 48 hours post dose and PK parameters were calculated using noncompartmental methods. BE was assessed in Cohorts 1 and 2 using geometric mean ratios (GMR) and associated 90% confidence interval (CI) bounds of 80%-125% (>85% power to conclude BE). In Cohort 3, only descriptive PK was assessed. Safety assessments were performed throughout study and during follow-up.

Results: Study treatments were generally well tolerated. All enrolled subjects (n=74) completed the study. No Grade 2, 3 or 4

adverse events were observed. Mean (%CV) and the GMR (90% CI) of EVG PK parameters are presented in Table 1. In Cohorts 1 and 2, EVG exposure (AUCLast, AUICinf, and Cmax) were within the protocol-defined BE bounds for both the pediatric tablet and suspension formulations vs the reference (adult) tablet formulation. In Cohort 3, EVG PK following multiple doses of EVG with RTV was comparable between pediatric tablet and suspension formulations and consistent with historical steady state data of boosted EVG, including achievement of mean trough concentrations (EVG Ctau) ~8.5 and 9.2-fold, respectively, above the IC95 (44.5 ng/mL).

Conclusions: EVG pediatric tablet and suspension formulations were each bioequivalent to adult tablets, when coadministered with RTV. The EVG formulations were well tolerated, and the multiple dose PK of both formulations were consistent with historical data of boosted EVG. As such, these study findings support evaluation of these pediatric formulations in HIV infected children.

903 CYP2B6 Polymorphisms Challenge Generalized FDA Efavirenz Dosing Guidelines in Children < 3 Yrs
Carolyn Bolton Moore1, Edmund Capparelli2, Pearl Samson3, Mutsa Bwakura-Dangarembizwa4, Patrick Jean-Philippe5, Carol Worrell6, Barbara Heckman7, Lynette Purdue8, Stephen A. Spector9, Ellen G. Chadwick10, IMPAACT P1070 team
1University of North Carolina Chapel Hill, Centre for Infectious Disease Research in Zambia, Lusaka, Zambia, 2University of California San Diego, San Diego, CA, United States, 3Harvard School of Public Health, Boston, MA, United States, 4University of Zimbabwe, Harare, Zimbabwe, 5Henry Jackson Foundation/ NIAID/ DAIDS, Bethesda, MD, United States, 6Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, United States, 7Clinical Pharmacy, University of California San Francisco, San Francisco, CA, United States, 8Frontier Science and Technology Research Foundation, Amherst, NY, United States, 9Northwestern University’s Feinberg School of Medicine, Chicago, IL, United States

Background: The FDA has published dosing recommendations for Efavirenz (EFV) in children less than 3 yrs of age based on safety, pharmacokinetic (PK), virologic and immunologic data from 3 open-label clinical trials. However, IMPAACT P1070 has found significant EFV PK variability in this age group due to a single genetic polymorphism in CYP2B6 516 (rs3745274); TT [Poor Metabolizers, PM] and GG or GT [Extensive Metabolizers EM]. P1070 preliminary data suggest that FDA recommended dosages will result in a high proportion of EFV exposures outside of the therapeutic range.

Methodology: IMPAACT P1070 is an ongoing, prospective, phase I/II open-label 24 wk trial of EFV as opened capsules in HIV-infected children (Cohort 1) and HIV/TB co-infected children (Cohort 2, not reported), ages 3 to <36 months. In Version (V) 1, a high initial dose of EFV (~1600 mg x (weight in Kg/70)0.7 rounded for weight band dosing) was used to produce a target AUC of 35-180 mcg*c/hr/mL, a systemic exposure similar to that shown to be effective and safe in older children and adults. Genotypic testing was performed in real-time from dried blood spots using a TaqMan probe assay and genotypic profile determined using allelic discrimination plots. 24 hour plasma PK data at week 2 were grouped by CYP2B6 516 genotype. Based on excessive exposures found in PMs in V1, dosages for PMs were reduced by 75% (~400 mg x (weight in Kg/70)0.7) rounded for weight band dosing/week dosing (target 1-4 mcg/mL). The AUC data for P1070 and FDA dosing are presented below:

Results: 38 subjects have had 24 hr PK evaluation; 29 CYP2B6 EM and 9 CYP2B6 PM. Median apparent clearance (CL/F) was 0.45 L/h/kg in the EM subjects but only 0.087 L/h/kg in the PM subjects. The median C24 for EM/PM was 1.8/4.2 mcg/mL for P1070 dosing and 0.9/8.5 mcg/mL for FDA dosing (target 1-4 mcg/mL). The AUC data for P1070 and FDA dosing are presented below:

Conclusions: Based on PK results from P1070, it appears that the FDA recommended doses of EFV will produce sub-therapeutic EFV AUCs in 38% of children <3 yrs who are extensive metabolizers (EM prevalence ~93% in Europeans and 80% of African Americans) and excessive AUCs in 67% of PM’s. In contrast, CYP2B6 genotype directed dosing allowed for 83% of PM and 89% of EM children to achieve target EFV PK levels. Given the importance of achieving appropriate drug levels in this population, CYP2B6 genotyping prior initiation of EFV will help optimize dosing in this age group.

904 High Nevirapine and Low Lopinavir/Efavirenz Exposures in Resource-Poor Ugandan Children
Imke H. Bartelink1, Rada M. Savic2, Grant Dorsey3, Henriette J. Scherpbier4, Edmund Capparelli5, Jane Achan6, Albert Plony6, Moses Kanya6, Diane Havlir7, Francesca T. Aweka1
1Bioengineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA, United States, 2Medicine, University of California San Francisco, San Francisco, CA, United States, 3Pediatrics, Emma Childrens Hospital AMC, Amsterdam, Netherlands, 4Center for Immunity, Infection & Inflammation, University of California San Diego, La Jolla, CA, United States, 5Medicine, The Makerere University, Kampala, Uganda, 6Center for AIDS Prevention Studies, University of California San Francisco, San Francisco, CA, United States, 7Clinical Pharmacy, University of California San Francisco, San Francisco, CA, United States

Background: Malnutrition may impact antiretroviral (ART) pharmacokinetics (PK) and clinical response in children. We evaluated the PK of nevirapine (NVP), efavirenz (EFV) and lopinavir (LPV) by nutritional status among HIV-infected children stabilized on ART in Tororo, Uganda.

Methodology: Sparsely sampled dried blood spot (DBS) ART samples, collected in Ugandan children residing in resource poor country (RPC) were corrected using hemoglobin and % protein bound to generate plasma concentrations, and then analyzed in the context of previously published rich PK-data from children from resource-rich countries (RRC) (United States, the Netherlands and France). Analysis was performed used nonlinear mixed-effects
905 Bone and Renal Safety at 96 Weeks of TDF-Containing Regimens in HIV-Infected Thai Children

Wasana Prasitsuebsai1, Thanyawee Puthanakit1, 2, Tanakorn Apornpong1, Siriwat Keadpudsai1, Torsak Bunupuradath1, Thongsuai Chuanjaroen1, Narukjaporn Thammajaruk1, Thidarat Jupimai1, Stephen J. Kerr1-3, Jintanat Ananworanich1, 4
1HIV-NAT, TRCARC, Bangkok, Thailand, 2Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, 3The Kirby Institute, University of New South Wales, Sydney, Australia, 4HIV-NAT, SEARCH, TRCARC, Bangkok, Thailand

Background: Tenofovir (TDF) is currently recommended in first- and second-line ART regimens for children. This study was aimed at determining the impact of TDF on bone mineral density (BMD) and renal function among HIV-infected adolescents after 96 weeks.

Methodology: Of 62 HIV-infected children on TDF-containing regimens, 35 children had CD4, HIV-RNA, BMD and renal function assessments over 96 weeks. An additional 27 children had cross-sectional renal toxicity assessments and mid-dose plasma TDF concentrations at 10-14 hours after dosing. Renal function. Longer duration of TDF treatment, concomitant PI use and higher mid-dose TDF concentrations were associated with renal abnormalities. Using current WHO dosing guidelines, simulations based on study results indicate that TDF minimum concentrations (Ctough) may exceed a maximum recommended Ctough of 8 mg/L in 67% of malnourished children. However, EFV and LPV dosing should result in appropriate Ctoughs in most Ugandan children.

Conclusions: Children residing in the resource poor area of Uganda exhibit high levels of malnutrition and show increased NVP and reduced EFV and LPV PK exposure compared to children from RRC. WHO guided dosing in Ugandan children, especially those malnourished may result in excessive NVP exposure while EFV and LPV exposure is expected to fall within target values. Further studies investigating the clinical impact of these PK changes during malnourishment is required, using more dense data and better knowledge of adherence, especially for NVP.

906LB Safety and Efficacy of Dolutegravir in HIV Treatment-Experienced Adolescents: 48-Week Results

Rolando M. Viani1, Carmelita Alvero1, Terry Fenton1, Edward Acosta1, Rohan Hazra1, Ellen O’Gara2, Barbara Heckman3, Debra McCarty-Steimers1, Sherene Min4, Andrew Wiznia1
1University of California San Diego, La Jolla, CA, United States, 2Harvard School of Public Health, Boston, MA, United States, 3University of Alabama, Birmingham, Birmingham, AL, United States, 4Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, MD, United States, 5National Institutes of Health, NIAID, DAIDS, Bethesda, MD, United States, 6Frontier Science and Technology Research Foundation, Amherst, NY, United States, 7GlaxoSmithKline, Research Triangle Park, NC, United States, 8GSK, Research Triangle Park, NC, United States, 9Jacobi Medical Center, Bronx, NY, United States

Background: P1093 is an ongoing Phase I/II multicenter open-label pharmacokinetic (PK), safety, dose finding study of dolutegravir (DTG) plus optimized background regimen (OBR) added after intensive PK (~Day 5-10); Stage 2: DTG was started with an OBR. Safety, tolerability, CD4 cell count and HIV-1 RNA were evaluated at Week 48. Virologic success was defined as achieving an HIV-1 RNA < 400 c/mL by Week 48 based on the FDA snapshot algorithm, with an additional secondary outcome of HIV-1 RNA <50 c/mL.

Methodology: HIV infected treatment experienced children ≥12 to <18 yrs on a failing antiretroviral (ARV) regimen with an HIV RNA of ≥1000 copies/mL (c/mL) were enrolled in Stage 1 (intensive PK) or Stage 2 (no PK, safety and efficacy). Stage 1: DTG was added to a stable, failing ARV regimen, with an OBR added after intensive PK (~Day 5-10): Stage 2: DTG was started with an OBR. Safety, tolerability, CD4 cell count and HIV-1 RNA were evaluated at Week 48. Virologic success was defined as achieving an HIV-1 RNA < 400 c/mL by Week 48 based on the FDA snapshot algorithm, with an additional secondary outcome of HIV-1 RNA <50 c/mL.
Results: Twenty-three adolescents (Stage 1, n=10; Stage 2, n=13) were enrolled and 22 (95.7%) completed the 48 week study visit. Demographics were as follows: 78% (18/23) female, 52% (12/23) African American, 35% (8/23) Caucasian, 26% (6/23) were of Hispanic ethnicity. Median age (range) was 14 yrs (12, 17) and median weight (range) was 52.2 kg (33, 91). Median (IQR) baseline CD4+ cell count and % were 466 cells/μL (297, 771) and 22% (18.4, 29.2), respectively. Median (IQR) baseline HIV-1 RNA log10 was 4.3 log10 copies/mL (3.9, 4.6). Nineteen adolescents received 50 mg/day and 4 received 35 mg/day of DTG. Virologic success, an HIV RNA < 400 c/mL was achieved in 73.9 % (17/23; 95% CI: 51.6 % to 89.8%) at Week 48. Additionally, 60.9% (14/23; 95% CI: 38.5% to 80.3%) had an HIV RNA load <50 c/mL at Week 48. Median (IQR) gain in CD4 cell count and % at Week 48 was 84 cells/μL (-81, 238) and 4.7% (0, 9.4) respectively. DTG was well tolerated, with 2 subjects experiencing Grade 3 laboratory abnormalities: one developed unconjugated bilirubin elevation while on atazanavir as part of the OBR, and another subject developed asymptomatic lipase elevation, which was deemed treatment unrelated. One subject discontinued DTG after virologic failure due to inability to meet study related appointments. Invariably, all participants who experienced virologic failure had incomplete adherence based on three day pill recall questionnaire. There were no Grade 4 AEs, SAEs or discontinuations due to AEs.

Conclusions: DTG plus OBR was safe and well tolerated in HIV infected adolescents. In addition, DTG treatment as part of an OBR provided good virologic efficacy through Week 48.

907 Simulation and Exposure-Based Assessment of Pediatric Lopinavir Fixed-Dose Combination Product
Saïk Urien1, Naim Bouazza2, Frantz Foissac3, Florian Fauchet1, David Burger1, Jean-René Kiechel1, Edmund Capparelli4, Jean-Marc Telayer1, Marc Lallemant1
1Cochin Hospital, Paris, France, 2Radboud University, Nijmegen, Netherlands, 3Drugs for Neglected Diseases Initiative, Geneva, Switzerland, 4University of California San Diego, La Jolla, CA, United States

Background: Currently, only one boosted PI is approved for use in infants: lopinavir/ritonavir (LPV/r). The LPV/r formulation is not ideal for infants and children living in resource-poor settings, as it is poorly tolerated, needs refrigeration, contains large amounts of undesirable excipients, and is more expensive than other regimens for most national HIV programmes. The development of low-cost, solid fixed-dose combinations of LPV/r with various nucleoside reverse transcriptase inhibitor (NRTI) backbones in modular unit forms (LPV/ABC/3TC and LPV/ZDV/3TC) is thus greatly needed to improve both management and adherence of children especially in resource-limited settings.

Methodology: The pharmacokinetic (PK) analysis combined 25 datasets including therapeutic drug monitoring and published clinical studies from IMPAACT and PENTA. Intensive and sparse PK data totaling 1394 LPV concentrations from 338 subjects, aged 2 days to 24 years old, were analysed. For 3TC, ABC, and ZDV, a total of 927 patients with 3820 concentrations, 188 patients with 1232 concentrations, and 756 patients with 3312 concentrations were used, respectively. Population PK analyses were performed for each drug using MONOLIX 4. Simulations of current dosing recommendations were performed to assess their ability to provide optimal exposure in children weighing 4 to 25 kg. For the NRTIs, dose ratios of 0.375 and 2 were respectively used for 3TC to LPV and ZDV-ABC to 3TC.

Results: After allometric scaling, a PK age effect was observed for all drugs. This age effect described increasing apparent clearance for all NRTIs and increasing bioavailability for LPV with age. The simulations indicated that the WHO dosing recommendations resulted in more than 95% of subjects with LPV Cmin > 1.0 mg/L. However, using the recommended drug ratios, the combination dosage for the 4-6 kg weight band (LPV/ZDV: 120/90mg BID) resulted in high ZDV exposure with more than 20% of subjects at levels associated with high risk of neutropenia (Cave>0.8 mg/L). Reducing the LPV/ZDV dosage to 80/60 mg BID dramatically decreased frequency of high ZDV concentrations and risk of neutropenia. This dosage reduction retained LPV Cmin >1.0 mg/L in more than 95% of subjects and did not adversely affect therapeutic target obtainment for the NRTIs. Moreover, this proposed dosage fully corresponded to the WHO guidelines for all NRTIs.

Conclusions: These simulations suggest that a pediatric fixed-dose LPV/3TC/ZDV or ABC formulation could be developed to achieve targeted therapeutic levels for all ARV components. Each unit would include 40 mg LPV, 10 mg RTV, 15 mg 3TC and 30 mg ABC or ZDV. According to the weight bands, i.e. 4-6 kg, 6-10 kg, 10-14 kg, 14-20 kg, 20-25 kg, therapeutic doses would be 2, 3, 4, 5, or 6 units twice daily of this formulation.

908 Bioequivalence of Two Pediatric Formulations vs Adult Tablet Formulation of Cobicistat
Joseph M. Custodio1, Xiang Yin1, Hiba Graham2, Mischa Hepner2, Joanna Koziara3, Erin Quirk3, Brian P. Kearney1, Sririvasan Ramanathan1
1Clinical Pharmacology, Gilead Sciences, Foster City, CA, United States, 2Biometrics, Gilead Sciences, Foster City, CA, United States, 3Clinical Research, Gilead Sciences, Foster City, CA, United States, 4Formulations Process Development, Gilead Sciences, Foster City, CA, United States

Background: There are limited antiretroviral pharmacoenhancers available for pediatric use. Cobicistat (COBI) is a mechanism-based CYP3A inhibitor devoid of antiretroviral activity approved for adults as a pharmacoenhancer of atazanavir 300 mg or darunavir 800 mg in the European Union and as a pharmacoenhancer in the single tablet regimen elvitegravir/COBI/emtricitabine/tenofovir disoproxil fumarate (ECF/TDF; Stridbild™) for treatment of HIV-1 infection in numerous countries. This study evaluated the pharmacokinetics (PK) of COBI administered as a 50 mg pediatric immediate release tablet (test) and as a 20 mg pediatric dispersible tablet (test) vs the 150 mg adult tablet formulation (reference).

Methodology: This was a prospective, open-label, randomized, multiple cohort, single dose, crossover study in healthy adult subjects. Cohort 1 (n=32) evaluated the pharmacokinetics (PK) of the pediatric immediate release tablets (3 X 50 mg) vs reference. Cohort 2 (n=30) evaluated the PK of the pediatric dispersible tablet (7.5 X 20 mg: tablet split using standard pill cutter) vs reference. All treatments were administered under fed conditions with 240 mL of water. Intensive PK sampling was conducted over 48 hours post dose and PK parameters were calculated using noncompartmental methods. Bioequivalence (BE) was assessed in both Cohorts using geometric mean ratios (GMR) and associated 90% confidence interval (CI) bounds of 80%-125% (>90% power to conclude BE). Palatability was assessed by questionnaire after each treatment. Safety assessments were performed throughout the study and during follow-up.
**Results:** Study treatments were generally well tolerated and all enrolled subjects completed the study, except one subject whom withdrew consent. All adverse events (AE) were Grade 1, with one subject experiencing Grade 2 AE while receiving the pediatric immediate release tablets. Mean (%CV) and the GMR (90%CI) of COBI PK parameters are presented in Table 1. COBI exposure (AUClast, AUCinf, and Cmax) were within the protocol-defined BE bounds for both the pediatric immediate release and dispersible tablet formulations vs the reference (adult) tablet formulation.

**Conclusions:** Pediatric formulations of COBI, administered either as 50 mg immediate release tablets or as 20 mg dispersible tablets, were each bioequivalent to the COBI adult tablet formulation, supporting evaluation of these pediatric formulations in HIV infected children.

**Background:** The integrase inhibitor-based E/C/F/TDF single-tablet regimen (STR) contains elvitegravir (EVG) 150 mg, the pharmacoenhancer cobicistat (COBI) 150 mg, emtricitabine (FTC) 200 mg and tenofovir disoproxil fumarate (TDF) 300 mg. The PK, efficacy, and safety of E/C/F/TDF were evaluated in adolescents in the initial Part A of a prospective, 48-week, single-arm, open-label trial.

**Methodology:** Treatment-naive patients 12 to <18 years of age, weighing ≥35 kg with HIV-1 RNA > 1000 copies/mL (c/mL), CD4 counts > 200 cells/µL and eGFR ≥90 mL/min received one E/C/F/TDF tablet once daily. Intensive PK was performed on Day 10 (steady state). The primary endpoint was EVG AUCtau. Exposures were compared to population PK-based exposures in adults from E/C/F/TDF Phase 2 and 3 trials by ANOVA. HIV-1 RNA, adverse events (AE) and routine laboratory tests were assessed through Week 12.

**Results:** Part A enrolled 14 subjects (64% male, 29% Asian, 64% black and 7% white) with a median age of 16 years (range: 13-17), a median weight of 57 kg (range: 35-80), and a median BMI of 21 kg/m² (range: 17-26). At baseline, geometric mean HIV RNA was 4.83 log₁₀ c/mL; 4 subjects (28.6%) had HIV RNA >100,000 c/mL, and median CD4 count was 442 cells/µL. At Day 10, the EVG geometric least squares mean (GLSM) AUCtau was 130% of the adult level (90% CI: 105-162%) and the GLSM Cmax was 124% of the adult level (90% CI: 116-173%). The GLSM Cτ was 410 ng/mL, 106% of the adult level (90% CI: 70.0-160%) and 9.2 times the protein-adjusted IC₉₅ of 44.5 ng/mL. COBI, TDF and FTC exposures were similar to exposures in adults. Among 11 subjects with data at Week 12, geometric mean HIV RNA was 1.61 log₁₀ c/mL, 100% of subjects had HIV RNA < 400 c/mL, 9/11 (81.8%) had HIV RNA <50 c/mL, and median CD4 count was 643 cells/µL (Figure). No subject met the criteria for virologic failure. The most frequent AEs were gastrointestinal (7/14, 50%). Related AEs were mild and included vomiting (2), abdominal pain (1), nausea (1), and headache (1). No AE led to discontinuation. Median serum creatinine (Cr) increased by 0.07 mg/dL at Week 12, similar to the increase seen in adults and consistent with COBI’s inhibition of tubular Cr secretion. No cases of renal tubulopathy or renal failure occurred.

**Conclusions:** In adolescents, the E/C/F/TDF STR provides component ARV exposures similar to adults, exhibits robust antiviral activity, and appears well tolerated. These findings support continued evaluation of this integrase inhibitor-containing STR in pediatric populations.
Complex Pattern of Inflammatory Biomarkers After ART Initiation in HIV-Infected African Children

Nigel Klein1, Chiho Berejeno2, Godfrey Pimundu3, Pietro Pala4, Tichaona Vhembo5, Victor Musiime6, Philip Kasirye6, Hannah Poulsom7, Ann Sarah Walker8, Andrew J. Prendergast9, and the ARROW Trial Team

1Institute of Child Health, London, United Kingdom, 2University of Zimbabwe, Harare, Zimbabwe, 3Joint Clinical Research Center, Kampala, Uganda, 4MRU/UVR Uganda Research Unit on AIDS, Entebbe, Uganda, 5Baylor-Uganda, Kampala, Uganda, 6MRC/UVRI Uganda Research Unit on AIDS, Entebbe, Uganda, 7Queen Mary University of London, London, United Kingdom

Background: HIV infection is characterized by immune activation, likely driven by viral replication, microbial translocation, malnutrition and co-infections, particularly in sub-Saharan Africa. Although characterized in HIV-infected adults, changes in inflammatory biomarkers have not been well described in African children starting ART with advanced disease.

Methodology: 316 children/adolescents (median (IQR) age 5 (2,9) years, 67% WHO stage 3/4) initiating ART in the ARROW trial in Uganda/Zimbabwe were enrolled in a substudy measuring inflammatory biomarkers (CRP, TNF-α, IL-6, sCD14) by ELISA on cryopreserved plasma at enrolment and then every 24 weeks to 192 weeks. VL was assayed using Abbott Taqman and Roche Amplicor, with lower detection limit 80 c/ml. Log10 absolute cytokine levels after ART initiation were modelled using random effects models with child-level intercepts and slopes, adjusting for site performing the assay.

Results: At ART initiation, geometric mean CD4% was 10.2%, VL 209261 c/mL, CRP 4.8 mg/L, TNF-α24.3 pg/mL, IL-6 6.6 pg/mL, and sCD14 1.9106 pg/ml. Children with lower pre-ART CD4% had higher pre-ART CRP (p=0.01), IL-6 (p<0.001) and sCD14 (p=0.005), but there was no association with pre-ART TNF-α (p=0.77). In contrast, children with higher pre-ART VL had significantly higher TNF-α (p<0.001), higher IL-6 (p<0.001) and higher sCD14 (p=0.006), but there was only weak association with CRP (p=0.09). VL suppression <80 c/ml was achieved by 79% children at 24 weeks; then 74%, 67%, 68%, 65% and 64% at 48, 72, 96, 144 and 196 weeks. IL-6 dropped by 32% [95% CI 24-41%] over the first 24 weeks on ART (p<0.001), but did not change significantly thereafter (p=0.87). CRP dropped by 48% [35-60%] over the first 48 weeks on ART (p<0.001), again with no evidence of change thereafter (p=0.87). TNF-α dropped by 70% [66-74%] over the first 48 weeks on ART, but then rose again by 47% [39-55%] to week 72, subsequently declining more modestly by 38% [33-42%] every 24 weeks (all p<0.001). This effect was seen independently in each site conducting assays, and in all pre-ART CD4% groups sCD14 declined much more slowly throughout follow-up, dropping by only 1% [1-2%] every 24 weeks (p<0.001).

Conclusions: Children starting ART with advanced disease have elevated inflammatory biomarkers, which are related to pre-ART CD4 levels (except for TNF-α). All biomarkers dropped after starting ART, although declines in sCD14 were very slow. IL-6 and CRP tended to drop rapidly and plateau after 24-48 weeks; by contrast, TNF-α showed more variability, perhaps in response to changes in VL. Better understanding changes in inflammatory biomarkers on ART may help to define subgroups of children with residual immune activation, who would benefit from adjunctive treatment strategies.

Preferential Preservation of Helios+Foxp3+ Regulatory T Cell Subset in HIV-Infected Children

Guenet Degaffe, Ramia Zakhour, Weihe Zhang, German Contreras, Cynthia Bell, Gihen Rodriguez, Gabriela Del Bianco, James Murphy, Gloria P. Heresi, Dat Q. Tran

Background: Foxp3+ regulatory T cells (Tregs) are a unique subset of CD4+ that play a critical role in immune homeostasis and tolerance. Most Tregs in peripheral blood are generated in the thymus; the remainder is induced in the periphery. Data are limited on the impact of HIV infection on Tregs, but none exist for Helios+Tregs in children with HIV infection. Since thymic function is highly active during childhood and can be severely damaged by HIV infection, our study investigated Tregs and their Helios+ subset in children with perinatally acquired HIV infection.

Methodology: A prospective cross-sectional cohort study was made on HIV infected children and adolescents receiving care through UTHealth. The study was IRB approved and required informed consent. Sample processing, FACS and data processing were by established methods and with commercially available reagents. Foxp3 and Helios intracellular staining was performed with an eBioscience kit. Tregs were defined as Foxp3+ within CD4+ T cells and the Helios+Tregs as Helios+ within Tregs.

Results: 59 patients were enrolled: median age 14.4 (range 0.8-21.3 years); 48.3% female; and 70% black (30% Hispanic/other). Most had previous clinically severe HIV (55% CDC Immune Status >1, CD4 nadir 18%, 371/μl, medians) but were clinically improved at the time of study (CD4+ 32%, 794/μl). Most (83.8%) were on cART at the time of Treg measurement. %Tregs negatively correlated with %CD4 (r=-0.439, p<0.001) while their numbers also negatively correlated with %CD4 (r=-0.321-0.477, p<0.01). When the patients were segregated into three groups, good (n=24, ≥25% CD4, <20 HIV RNA copies/ml), intermediate (n=26, ≥25% CD4, >20 HIV) and poor (n=9, <25% CD4, >20 HIV), those with the highest %Tregs were in the poor, but the %Helios+Tregs was similar in all groups. The poor group also had the highest ratio of % and # of Tregs to CD4+ cells.

Conclusions: There is a selective expansion or survival of Tregs associated with CD4 depletion and increased viremia. This preservation of Tregs is within the Helios+ subset, which could be reconstituted from the thymus. While this expansion appears ineffective in suppressing immune activation, it might be important in regulating autoimmunity.
912 Perturbation of Regulatory T Cell Subsets in HIV Infected Children

Alka Khaitan1, Mussa Mwamzuka2, Fatma Marshed2, Adam Kravietz2, Tiina Ilmet1, Swale Said2, Aabid Ahmed2, William Borkowsky2, Derya Unutmaz4

1Pediatrics, Division of Infectious Diseases and Immunology, New York University School of Medicine, New York, NY, United States, 
2Bomu Hospital, Mombasa, Kenya, 
3Microbiology, New York University School of Medicine, New York, NY, United States, 
4Microbiology, Pathology, Medicine, New York University School of Medicine, New York, NY, United States

Background: Regulatory T cells (Tregs) mediate immune tolerance during autoimmune disease and chronic infections. During HIV infection, Tregs may act either beneficially to curtail immune activation or pathologically to suppress HIV-specific immune responses. Previous reports of Tregs during chronic HIV have conflicting results with higher or lower levels compared to controls. Identifying true Tregs with suppressive activity proves challenging during HIV infection, as traditional Treg markers, CD25 and FOXP3, may transiently upregulate expression as a result of immune activation. Helios is a recently identified transcription factor that marks natural Tregs with suppressive activity. Moreover FOXP3+Helios+ CD4 T cells do not produce the cytokine IL-17, and have been called “bona fide” Tregs. We sought to identify these bona fide Tregs in vertically infected HIV positive children.

Methodology: We evaluated Treg levels by flow cytometry in the peripheral blood of 60 children from Bomu Hospital in Mombasa, Kenya. The cohort included age-matched children between 3 to 12 years old in the following categories: HIV negative (HIV-), HIV positive antiretroviral therapy naïve (ART-), and HIV positive on antiretroviral therapy (ART+). Peripheral blood mononuclear cells (PBMCs) were isolated and cryopreserved from each subject. Thawed PBMCs were stained for surface antibodies CD3, CD4, CD25, CD38, CD45RO, and intracellular transcription factors FOXP3 and Helios. All statistical analysis was performed with GraphPad Prism software using Mann-Whitney or Spearman’s correlation tests.

Results: HIV+ children (ART- and ART+) expressed higher levels of FOXP3 and Helios in CD4 T cells compared with HIV- controls (ART-: p=0.0012, ART+: p=0.0057). FOXP3+Helios+ expression inversely correlated with the percent of CD4 T cells (p<0.0001, r=-0.4883), despite nearly normal CD4 levels in ART+ children. As previously reported, HIV infected children had higher immune activation as measured by CD38+HLA-DR+ expression on CD8+ T cells (ART-: p<0.0001, ART+: p=0.0223). This immune activation (CD38+HLA-DR+ CD8 T cells) positively correlated with FOXP3+Helios+ Treg levels (p=0.0008, r=0.4301). The ART+ group also demonstrated an activated phenotype by increased CD38 expression in memory (p=0.0001) and in FOXP3+Helios+ memory CD4 T cells (p=0.0010) that was not present in the ART+ subjects.

Conclusions: Bona fide Treg levels increase during HIV infection and correlate with waning CD4 T cells and higher immune activation. While antiretroviral therapy decreases the activated state in these bona fide Tregs, it does not restore Treg levels to the homeostatic proportion in HIV negative children. This increase in Helios+ Tregs may act to ameliorate chronic immune activation during HIV infection.

913 Incomplete Immune Reconstitution in HIV-1-Infected Children With Virological Suppression

Paul Krogstad1, Kunjal Patel1, Brad Karalius2, Mark Abzug1, James Oleske4, George Seage2, Andrew Wiznia5, Rohan Hazra2, Russell Van Dyke1, for The Pediatric HIV/AIDS Cohort Study and NISDINvestigators

1Pediatrics and Pharmacology, David Geffen School of Medicine, UCLA AIDS Institute, Los Angeles, CA, United States, 
2Harvard School of Public Health, Boston, MA, United States, 
3University of Colorado/Children’s Hospital Colorado, Aurora, CO, United States, 
4Rutgers University, Newark, NJ, United States, 
5Albert Einstein School of Medicine, Bronx, NY, United States,

Background: Suppression of plasma viremia by antiretroviral therapy (ART) is generally associated with improvements in immunological status, but some individuals fail to achieve normalization of CD4 T cell counts. In adults, AIDS defining events rapidly decrease once virological suppression is achieved, even when CD4 T cell lymphocytopenia persists. Similar data are not available for children to determine the frequency of and risks associated with persistence of CD4 lymphocytopenia despite effective ART.

Methodology: Data were pooled from 3,784 children enrolled in the 219C, NISDII and AMP cohorts, and 933 perinatally HIV-1 infected youth were identified with virologic suppression (VS) lasting at least 1 year at an age of ≥5 years, with available CD4 counts. For each child’s first period of virologic suppression (VS) (plasma HIV RNA < 400 copies/ml), piecewise linear regression models were used to examine CD4 T cell trajectories during VS by CD4 at start of VS and Kaplan-Meier estimates for time to CD4≤500 cells/μL were generated for CD4 categories < 500 copies/μL.

Results: Of the 933 children in the study population, 50% were black, 36% Hispanic/Latino, and 14% white/Asian with a median age of
8.8 years at the start of ART that resulted in VS. 108 (12%) were from NISDI sites in Argentina, Brazil, Mexico, and Peru; 88% were from the United States and Puerto Rico. At the start of ART leading to VS, 92 (10%), 118 (13%), and 138 (15%) had CD4 T cell counts of <200, 200-350, and 350-499 cells/μL, respectively. Most (99%) children achieved a CD4 count of 200 cells/μL after 1 year of VS, but 13% failed to exceed 500 cells/μL. The rate of initial increase in CD4 T cell counts was inversely proportional to baseline CD4 T cell strata. The median times to first CD4 T cell counts >500/μL were 15, 9, and 6 months for children with <200, 200-350, and 350-499 CD4+ T cells/μL at the time of VS (Figure). CDC C events occurred in 8 children after VS, including encephalopathy, bacterial peritonitis, pneumonia, and candida esophagitis. 3 such events occurred in the first 6 months following VS; the others occurred 6.6 to 21 months after VS. 5 events were in children with CD4 T cell counts >500 cells/μL.

Conclusions: Most children who maintain virological suppression improve their CD4 T cell counts. The time to achieving a CD4 count of ≥ 500 cells/μL is highly variable and depends upon CD4 counts at the start of VS. Although rare, AIDS defining events continued to occur in 1% of the population studied, despite VS and improved T cell counts.

914 Lower Inflammatory Biomarkers in Children Randomized To Prolonged Cotrimoxazole Prophylaxis
Andrew J. Prendergast1, Mutsawashe Bwakura Dangarembizi2, Victor Musilme3, Joseph Lutaakome4, Adeoda Kakitiniwa2, Godfrey Pimundu2, Annie Shonhai2, Moira Spyer5, Nigel Klein6, Ann Sarah Walker6, and the ARROW Trial Team
1Queen Mary University of London, London, United Kingdom, 2University of Zimbabwe, Harare, Zimbabwe, 3Joint Clinical Research Center, Kampala, Uganda, 4MRC/UVRI Uganda Research Unit on AIDS, Entebbe, Uganda, 5Baylor-Uganda, Kampala, Uganda, 6MRC Clinical Trials Unit, London, United Kingdom, 7Institute of Child Health, London, United Kingdom

Background: Cotrimoxazole (CTX) prophylaxis reduces morbidity and mortality in HIV-infected children on long-term ART, despite high-level pathogen resistance. Children taking CTX also have improved growth and reduced anemia, for reasons that are unclear. We hypothesized that benefits of CTX may be partly driven by reductions in inflammation.

Methodology: 758 children/adolescents (median (IQR) age 7 (4,11) years) in the ARROW trial in Uganda/Zimbabwe were randomized to stop (n=382) vs continue (n=376) daily CTX after median (IQR) 3.3 (2.1,3.8) years on ART. Inflammatory biomarkers (CRP, TNF-α, IL-6, sCD14) were measured by ELISA on cryopreserved plasma in a subset of 304 children at randomization (155 stop, 149 continue), then at 12, 24, and 96 weeks. Those co-enrolled in a cross-sectional metabolic substudy also had albumin, total protein and lipid profile measured 3 years after ART initiation. Change in log10 cytokine levels after randomization were modelled using normal interval regression, adjusting for site performing the assay.

Results: CRP was significantly higher in those randomized to stop CTX at 12, 24 and 96 weeks after ART initiation (2.22-fold [95% CI 1.23-4.01], p=0.008; 1.98-fold [1.26-3.14], p=0.003; and 1.95-fold [1.10-3.46], p=0.02, higher, respectively; N=193, 260, 192 to date). There was a trend towards higher TNF-α in the stop CTX group at week 12 (1.16-fold higher vs continue [0.99-1.36], p=0.07), but this attenuated at 24 weeks (p=0.19) and had disappeared at 96 weeks (p=0.30). For sCD14 and IL-6, there was no evidence of a difference between stop vs continue CTX groups at week 12 (p=0.16 and p=0.17 respectively); by 24 weeks differences had widened (difference stop vs continue: sCD14 1.10-fold higher [1.00-1.21], p=0.06; IL6 1.35-fold higher [0.99-1.84], p=0.06), but were absent at week 96 (sCD14 p=0.91; IL-6 p=0.34). At a single measurement taken at median 48 (IQR 36-60) weeks after randomization in 169 children, albumin was also significantly lower in those randomized to stop CTX (difference -1.77 g/L vs continue [-2.97,-0.57] p=0.004), with non-significant trends towards higher total protein (+1.76 g/L vs continue [-0.13,+3.66] p=0.07) and LDL cholesterol (+0.17mmol/L vs continue [-0.04,+0.38] p=0.11).

Conclusions: Children on long-term ART randomized to stop CTX showed a rise in inflammatory biomarkers compared to those continuing CTX, in particular with increases in CRP persisting for two years after stopping prophylaxis. Previously reported benefits of CTX, particularly for anemia and growth, may therefore be partly driven by reductions in chronic inflammation, either directly through the well-described immunomodulatory properties of CTX, or indirectly through modulation of microbial translocation.

915 CD127 Expression On Naive T-Cells and HIV Replication in Youths Infected in the Perinatal Period
Daniel Scott-Algara1, Jérôme Le Chenadec2, Jociane Warszawski2, Thomas Montange2, Jean-Paul Viard2, Catherine Doillus3, Véronique Avettrand-Fenoeil4, Christine Rouzioux5, Stéphane Blanché1, Florence Buseyne1
1Virology, Institut Pasteur, Paris, France, 2CESP INSERM U1018, Le Kremlin-Bicêtre, France, 3AP-HP, Paris, France, 4EA3620, Université Paris Descartes, Paris, France

Background: In a cohort of youths infected with HIV-1 in the perinatal period, we previously reported that naive CD4 T-cell levels were in the same range as in uninfected individuals and that thymopoiesis was maintained in both viremic and aviremic patients. Here, we studied naive T-cell homeostasis by assaying plasma IL-7 and cellular expression of CD127, its high-affinity receptor.

Methodology: The ANRS-EP38-IMMIP study comprised 93 perinatally HIV-infected youths between 15 and 24 years old. At the time of the study, 85% were on HAART and 65% were aviremic. CD127 expression on T-cells was quantified by flow cytometry. Plasma cytokines were quantified by ELISA or multiplex assays. Mann-Whitney and Spearman tests were used for univariate analyses. Multivariate linear regressions were performed.

Results: Plasma IL-7 levels were significantly higher in viremic patients than in aviremic patients (4.5 vs. 3.9 pg/mL, P<0.02) and were negatively correlated with the CD4 T-cell counts in viremic patients (rho=-0.355, P=0.04), but not aviremic patients (rho=-0.137, P=0.31). CD127 expression on memory CD8 T-cells was lower in aviremic than viremic patients (41.6 vs. 59.8%, P=0.03) but CD127 expression on memory CD4 T-cells was similar (88.9 vs. 88.1, P=0.41). In sharp contrast, CD127 expression on naive CD4 T-cells was higher in viremic than aviremic patients (91.3 vs. 87.1%, P=0.007). In aviremic patients, the CD127hiCD4+ percentage was independently associated with the CD4 T-cell count (adjusted estimate per 100 cells: 1.2; 95%CI: 0.3; 2.0); the detection of plasma IFN-alpha (adjusted difference: 7.1; 95%CI: 2.4; 11.8) and the plasma sTNFR2 level (adjusted estimate per pg/ml: -0.010; 95%CI: -0.017; -0.003). However, it was not associated with the plasma IL-7 level or the naive CD4 T-cell percentage. For viremic
patients, the CD127hiCD4N percentage was significantly lower in patients with detectable plasma IL-4 (adjusted difference: -7.8; 95% CI: -14.2; -1.4), and was not associated with the CD4 T-cell count (adjusted estimate per 100 cells: -0.4; 95% CI: -1.6; 0.8). The expression level of CD127 on naive CD8 T-cells were similar to that on naive CD4 T-cells.

Conclusions: After at least 15 years of exposure to perinatally acquired HIV infection, adolescents and young adults have elevated expression of CD127 on naive CD4 T-cells in the presence of active HIV replication. This contrasts with the down-regulation of CD127 reported in viremic adults, but is consistent with the preservation of naive CD4 T-cell homeostasis in these young patients.

1SPED, Université Bordeaux Ségalen, Bordeaux, France; 2PACCI, Abidjan, Côte d’Ivoire; 3CHU d’Odonoto-Stomatologie, Bamako, Mali; 4Hôpital d’Enfants Albert Royer, Dakar, Senegal; 5PM Yopougon-Attié, Abidjan, Côte d’Ivoire; 6CCTOS, Abidjan, Côte d’Ivoire; 7Department of Orofacial Sciences, University of California San Francisco, San Francisco, CA, United States

**Background:** The prevalence of dental caries is believed to be higher among HIV-infected (HIV+) children than in the general pediatric population. However, dental caries are not described as opportunistic infections and the association between dental caries and HIV infection is unclear in the literature. The objective of this study was to assess the association between the number of decayed, missing and filled permanent and temporary teeth surfaces (DMF defs) and the HIV infection status among children in West Africa.

**Methodology:** A multi-center two-step cross-sectional survey was conducted within five clinical centers in Mali, Senegal and Côte d’Ivoire. A random sample of 5 to 15 years old HIV+ children in care and a sample of their non-infected siblings (HIV-) were recruited in 2011-2012. Seronegative status for HIV infection in this latter group was confirmed by ELISA tests conducted in the context of the national HIV program. Oral health data collection was conducted by five trained and calibrated dentists (Cohen’s kappa coefficient 0.59 to 0.93). The association between the DMF defs and the HIV infection status was analyzed using a zero-inflated negative binomial (ZINB) model.

**Results:** 420 HIV+ children (84 or 20.2% with CD4 count <350 cells/mm³) and 418 HIV- siblings aged 4.4 to 15.7 years-old were enrolled. HIV+ children were more likely to attend school (93.0%) than their HIV- siblings (86.4%), had less frequently sweet drink intakes (71.7% vs. 80.6%) and were more likely to have ≥3 meals per day (68.8% vs. 79.4%). The median DMF defs was 7 (interquartile range IQ: [2-15]) in HIV+ children and 2 (IQ: [0-7]) in HIV- siblings. The median defs and DMFS scores were respectively 5 and 2 in HIV+ children vs. 2 and 0 in HIV- children. The percentage of children affected with dental caries (%DMFdefs≥1) was significantly higher in HIV+ children (86.0%) than the non-infected ones (64.4%, p-value<0.001). The d- and D- components contributed to 94.8% of the DMF defs in HIV+ children and to 96.6% in HIV- children. The multivariate analysis showed that HIV infection was significantly associated with a higher probability of presenting dental caries. In children at-risk for dental caries, HIV+ children had a mean DMF defs significantly higher than HIV- children.

**Conclusions:** Even if HIV+ children seemed to be less exposed to common risk factors for dental caries, they were more affected. Dental care and prevention for oral health are needed for HIV+ children and have to be included in pediatric multidisciplinary care teams in order to decrease comorbidities.

**917 Preclinical Atherosclerosis in Eastern Africa: Results From a Pediatric Ethiopian Cohort**

Julia C. Rosebush1, Rudolph L. Gleason2, Alexander Cauth3, Daniel Seifu4, Allison Eckard4, Wokaebeba Taye4
1Pediatric Infectious Diseases, Emory University, Atlanta, GA, United States; 2Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States; 3Biochemistry, Black Lion Hospital, Addis Ababa, Ethiopia; 4Pediatrics, Black Lion Hospital, Addis Ababa, Ethiopia

**Background:** HIV-infected pediatric patients on antiretroviral therapy (ART) demonstrate an elevated incidence of dyslipidemia, lipodystrophy, and cardiovascular disease risk (CVD). Most studies, however, focus on cohorts from developed countries, with fewer data available for these co-morbidities in sub-Saharan Africa, where the prevalence of HIV-infected youths is much higher.

**Methodology:** Six- to 18-year-old age- and sex-matched HIV-infected subjects who were ART-naive (n=45), efavirenz (EFV)-treated (n=90), nevirapine (NVP)-treated (n=76), or ritonavir-boosted lopinavir (LPV/r)-treated (n=19) were recruited from Black Lion Hospital in Addis Ababa, Ethiopia. Pulse wave velocity (PWV) was assessed via applanation tonometry, as a measure of arterial stiffness, and carotid intima-media thickness (cIMT) and brachial artery flow-mediated dilation (FMD) were assessed via non-invasive ultrasound as a measure of subclinical atherosclerosis and endothelial function, respectively. Body mass index, waist-to-hip circumference ratio, and skin-fold thickness were used to characterize body composition. CD4+ cell count, fasting glucose, total-, HDL-, and LDL-cholesterol, triglycerides, and complete blood counts were measured. Results are presented as medians (interquartile range). Kruskal-Wallis non-parametric one-way ANOVA was performed to determine statistical significance across groups.

**Results:** PWV was elevated in LPV/r-treated subjects compared to EFV- and NVP-treated and ART-naive subjects [5.2 (4.6-5.9) vs. 4.7 (4.3-5.3), 4.6 (4.2-5.2), and 4.6 (4.1-5.0) m/s, respectively, p=0.016]. No differences in cIMT or FMD were observed across groups. LPV/r-treated subjects also exhibited elevated total- and LDL-cholesterol and total/HDL-cholesterol ratio compared to the other groups. EFV- and NVP-treated subjects exhibited elevated total-, LDL- and HDL-cholesterol, compared to ART-naive subjects; however, no differences were observed in total/HDL-cholesterol ratio between EFV-treated, NVP-treated, and ART-naive subjects.
918 Insulin Resistance in HIV-Infected Youth Is Associated With Decreased Mitochondrial Respiration

Jody K. Takemoto1, Jiajia Wang2, Denise L. Jacobson3, Tracie L. Miller1, Mitchell E. Oeffner4, Russell B. Van Dyke1, Daniel E. Libutti4, Patricia Graham1, Mariana Gerschenson1, for the Pediatric HIV/AIDS Cohort Study

1Cell and Molecular Biology, University of Hawaii, Honolulu, HI, United States; 2Harvard School of Public Health, Boston, MA, United States; 3University of Miami, Miami, FL, United States; 4Children’s Hospital Los Angeles, Los Angeles, CA, United States; 5Tulane University Health Sciences Center, New Orleans, LA, United States

Background: Antiretroviral therapy (ART) has dramatically reduced vertical HIV transmission and prolonged survival of HIV-infected children. However, these advances may lead to progressive long-term metabolic complications including insulin resistance (IR). We hypothesize that HIV and/or ART cause mitochondrial dysfunction, decreasing cellular respiration and thereby increasing oxidative stress and lactate/pyruvate levels, resulting in IR.

Methodology: A subset of children with perinatal HIV enrolled in the Pediatric HIV/AIDS Cohort Study were co-enrolled in a mitochondrial substudy. Fasting venous lactate, glucose, and insulin levels were measured. IR was defined by Homeostasis Model Assessment (HOMA-IR) >4.0. Mitochondrial respiration was measured from peripheral blood mononuclear cells utilizing the Seahorse XF24 analyzer (http://www.seahorsebio.com) in a random sample of 25 with IR (IR+) and 50 without (IR-). Unadjusted differences in mitochondrial respiration between IR+ and IR- were evaluated using the Wilcoxon rank sum test. Correlations between mitochondrial respiration (basal, ATP production, proton leak, maximal, spare, and non-mitochondrial respiration) and metabolic measurements were evaluated by Spearman correlation.

Results: IR+ were similar to IR- in age (median 16.5 v 15.6 yr), males (60% v 50%), Non-Hispanic black (68% v 72%), and current CD4 counts (574 v 686 cells/mm3). IR+ trended toward a lower nadir CD4 (12% v 17%, p=0.07) and a higher peak viral load (607K v 185K, p=0.07). There were no significant differences in past or current type of ART. Median venous lactate (1.5 v 1.1 mM, p<0.001), pyruvate (0.12 v 0.09 mM, p=0.003), and glucose (88 v 85 mg/dL, p=0.007) were higher in IR+. Furthermore, proton leak (585 v 790 pMoles, p=0.03), maximal respiration (1815 v 2499 pMoles, p=0.025), and spare respiratory capacity (1162 v 2017 pMoles, p=0.03) were significantly lower in the IR+ group. Basal respiration, ATP production, proton leak, maximal respiration, and spare respiratory capacity were negatively associated with HOMA-IR (p<0.009), while non-mitochondrial respiration was positively associated with glucose (p=0.02).

Conclusions: Insulin resistance is associated with lower mitochondrial respiratory activity in HIV+ youth. These findings provide a possible mechanism for metabolic dysfunction in HIV+ youth.

919 The Effect of Long-term Zidovudine On Hematological Parameters in the ARROW Randomized Trial

Victor Musiime1, Adrian Cook2, Patricia Nahiriya-Ntage3, Mutsawashe Bwakura-Dangarembizi4, Adeodata Kekitiinwa5, Margaret Thomason2, Richard Katuramu5, Philippa Musoke1, Ann Sarah Walker1, Diana M. Gibb2, and the ARROW Trial Team

1Joint Clinical Research Center, Kampala, Uganda; 2MRC Clinical Trials Unit, London, United Kingdom; 3MRC/UVRI Uganda Research Unit on AIDS, Entebbe, Uganda; 4University of Zimbabwe, Harare, Zimbabwe; 5Baylor-Uganda, Kampala, Uganda

Background: Both zidovudine (ZDV) and advanced HIV are associated with hematological abnormalities, but the relative contribution of each to toxicity in children initiating ART has not been described.

Methodology: 1206 ART-naïve Ugandan/Zimbabwean children were randomized to standard 3-drug NNRTI+3TC+ABC (no ZDV) vs 4-drug NNRTI+3TC+ABC+ZDV induction, decreasing at 36 weeks to 3-drug NNRTI+3TC+ABC (short-term ZDV) or to 3TC+ABC+ZDV (long-term ZDV). CD4 and hematology/biochemistry were done 12-weekly but results only routinely returned for half the children in a monitoring strategy randomization. Changes in hemoglobin, neutrophils and platelets after ART initiation, and incidence of grade 3/4 toxicity and hematology-related ART substitutions, were compared between randomized arms.

Results: Median follow-up was 4 years; 5%, 21%, and 95% follow-up was spent on ZDV in the no, short- and long-term ZDV arms respectively. Hemoglobin increased significantly in all arms at all time points. However increases were -0.5 g/dL smaller in long-term ZDV vs no ZDV arms throughout follow-up (p<0.001), with mean increases of 2.0 vs 1.5 g/dL respectively at 4 years. Following ZDV discontinuation at 36 weeks in the short-term ZDV arm, hemoglobin rebounded to levels seen in the no ZDV arm, with no evidence of permanent impairment. Graded toxicity was infrequent; 32 (8%) no, 36 (9%) short-term and 41 (10%) long-term ZDV children had grade 3/4 anemia during follow-up (p=0.61), and 15 (4%), 20 (5%), and 23 (6%) grade 4 (p=0.47). Despite similar incidence, anemia led to 0 vs 13 vs 14 ART modifications respectively. Neutrophils declined slightly over time in the no ZDV arm, but initiation of ZDV-containing ART was associated with an immediate drop in neutrophils of -0.6x109/L, a deficit which persisted throughout follow-up in the long-term ZDV arm, but was reversed on ZDV discontinuation in the short-term ZDV arm (p<0.001). 68 (17%), 105 (26%) and 136 (34%) children respectively ever had grade 3/4 neutropenia (p<0.001), and 10 (3%), 27 (7%), and 27 (7%) grade 4 (p=0.01). However, neutropenia led to only 0 vs 2 vs 4 ART modifications. In all arms, platelets increased sharply following ART initiation and then modestly declined; if anything declines were greater in the no ZDV arm (p=0.07). 19 (5%), 12 (3%) and 22 (5%) children respectively ever had grade 3/4 thrombocytopenia (p=0.20).

Conclusions: Incidence of severe anemia was similar regardless of ZDV use in a randomized comparison, strongly suggesting that its occurrence on ZDV-containing ART predominantly reflects HIV disease. ZDV was associated with severe neutropenia in a minority of children, although this rarely led to ART modification, reflecting uncertainty about the interpretation of low neutrophils in African children.
**920 Bone Quality Determination by Ultrasonometry in Young South African HIV-Infected Children**

Stephen M. Arpadi1, Stephanie Shiau1, Jonathan J. Kaufman2, Ashraf Coovadia2, Renate Strehlau3, Francoisine Pinillos4, Michael T. Yin1

1Columbia University, New York, NY, United States, 2Mount Sinai School of Medicine, New York, NY, United States, 3University of the Witwatersrand, Johannesburg, South Africa

**Background:** Skeletal abnormalities, including decreased bone mineral content and density (BMC; BMD) by dual-energy X-ray absorptiometry (DXA) have been described in children and adolescents with HIV-infection. Although DXA is the most common method for characterizing bone, it is not widely available in resource-constrained settings (RCS) where the majority of HIV-infected children reside. Quantitative ultrasonography (QUS) assesses bone quality by measuring the attenuation and speed of an ultrasound wave through bone. It does not require radiation exposure or high-level training, is portable, costs less than DXA to perform, and has a short scan time, making it potentially well-suited for assessing and tracking bone acquisition in RCS. Here, we evaluate the relationship between QUS and DXA in young South African HIV-infected children.

**Methodology:** Data for this analysis was obtained at outpatient study visits from CHANGES (Childhood HAART Alterations in Normal Growth, Genes, and aGeing Evaluation Study), a longitudinal cohort study of perinatally HIV-infected children who initiated ART before age 2 in Johannesburg, South Africa. BMC and BMD of the whole body and lumbar spine were measured by DXA (Hologic Discovery Wi bone densitometer) and analyzed using Apex Version 3.4 software. Speed of sound (SOS) and the broadband ultrasound attenuation (BUA) at the heel/calcaneus were obtained by QUS (Lunar Achilles Insight). Calcaneus stiffness index (SI) was calculated as per manufacturer: SI = (0.67 x BUA + 0.28 x SOS) - 420.

**Results:** Forty seven children with a mean age of 7.7 ± 1.2 years (age range 6.0 to 9.8 years), including 26 (55.3%) boys and 21 (44.7%) girls were evaluated. The mean weight-for-age z-score (WAZ) was -0.62 ± 1.0 and mean height-for-age z-score (HAZ) was -1.33 ± 1.0. Twenty one (44.7%) of the children were on a LPV/r-based regimen and 26 (55.3%) were on an EFV-based regimen. All children were also on two NRTIs, including 3TC and ABC or d4T, but not TDF. BUA was moderately correlated with whole body BMC (0.50, p<0.01) and BMD (0.49, p<0.01) as well as lumbar spine BMC (0.50, p<0.01) and BMD (0.48, p<0.01). SI was also moderately correlated with whole body BMC (0.40, p<0.01) and BMD (0.39, p<0.01) as well as lumbar spine BMC (0.37, p<0.01) and BMD (0.43, p<0.01). Independently, SOS did not have significant correlations with whole body or lumbar spine BMC and BMD.

**Conclusions:** In this sample of young children with HIV receiving ART, QUS BUA and SI correlate significantly with whole body and lumbar spine BMC and BMD. Although additional research is necessary, QUS may prove to be a valuable method to assess bone quality and acquisition in HIV-infected children in RCS.

**Response To Early ART Initiation in Infants**

**922 Routine Antibody Tests Have No Place in Determining HIV Status After Early ART: Evidence From CHER**

Helen Payne1, Nonhlanhla Mkhi Ze, Lynn Morris1, Kennedy Otwo mar6, Ravindra Panchia7, Avy Violari1, Nigel Klein1, Abdel G. Babiker5, Mark F. Cotton2, Diana M. Gibb1

1Infectious Diseases and Microbiology, Institute of Child Health, London, United Kingdom, 2Children’s Infectious Diseases Clinical Research Unit, Faculty of Medicine and Health Sciences, University of Stellenbosch, Cape Town, South Africa, 3Centre for HIV and STIs, National Institute for Communicable Diseases, Johannesburg, South Africa, 4Perinatal HIV Research Unit, University of the Witwatersrand, Johannesburg, South Africa, 5Clinical Trials Unit, Medical Research Council, London, United Kingdom

**Background:** HIV-1-infected infants starting early ART may become HIV-antibody seronegative following decay of passively acquired maternal antibody and suppression of viral replication. As ART guidelines recommend immediate ART for all HIV-infected children under 2 years, the frequency of seronegative status following early ART has management implications in young children.

**Methodology:** The randomised Children with HIV Early Antiretroviral Therapy (CHER) trial compared early limited with deferred ART (ART-Def) in HIV-infected infants &t12 weeks of age with baseline CD4 ≥25%. HIV infection was diagnosed by HIV DNA PCR confirmed with a RNA viral load >1000 copies/ml. Here we compare early ART until 96 weeks (ART-96W) with ART-Def. Median age at ART start was 23 weeks (IQR 18-32) for ART-Def versus 7 weeks (IQR 7-8) for ART-96W. HIV-1 antibody was measured in stored plasma from 75/125 ART-Def and 109/126 ART-96W children at median age 92 weeks (IQR 90.6 - 93.4) by 3 techniques: (1) 4th generation microparticle enzyme immunoassay HIV antigen/antibody combination; (2) HIV-1/2 qualitative immunochromatographic rapid antibody test assessed by an independent, blinded clinician; (3) a sensitive in-house ELISA to quantify anti-gp120 IgG and total lgG.

**Results:** Children in ART-Def had significantly more antibody than ART-96W in all 3 tests: automated serology (90% versus 54% seropositive, p=0.001), rapid test (88% versus 47%, p<0.001), and quantitative anti-gp120 lgG ELISA (median 6,870 μg/μl (IQR 1,706-53,645) versus 230 (IQR 133-13,129) p=0.04). Levels of total lgG were similar in both groups (p=0.28) indicating that this effect was specific to HIV responses. While all children had detectable anti-gp120 lgG antibody, 8 (10%) from ART-Def and 49 (46%) from ART-96W were seronegative using automated serology. In ART-Def, there was no difference between the automated and rapid test; however, in ART-96W 9 children with weakly positive automated results had negative rapid tests. In ART-Def, older age at ART initiation was associated with increased anti-gp120 lgG (p=0.002). By automated serology, starting ART between 12-24 weeks had a 13.7-fold higher odds of being seronegative by 92 weeks old, compared to starting ART aged 0-12 weeks (95% CI: 3.1 - 60.2, p=0.001); all 33 children starting ART >24 weeks of age were seropositive.

**Conclusions:** Almost half children starting ART within 12 weeks of life and 6% of those starting at 12-24 weeks were seronegative by commercial serology or rapid tests at ~2 years of age. Therefore, routine antibody tests should not be used to confirm HIV status among children already diagnosed and started on ART at <6 months of age. Whether persistence of anti-gp120 lgG represents slow decay or is a response to low levels of HIV replication, requires further study.
Different Profiles of HIV in Early Treated Children Seronegative by ELISA in Cameroon

Mathurin C. Tejokem1, Anfumbom Kfutwah2, Francis Ateba Ndongo3, Susie Tetang Ndiang4, Ida Calixte Penda5, Willian Mbarzouen2, Félicité Owona1, Josiane Warszawski6, Christine Rouixoux5, 6, Albert Fayet1, 12

Background: Recent data on early treated HIV-infected adults and infants, describing long-term virological control after treatment interruption has raised the possibility of a functional HIV cure. We aimed to explore residual HIV using ultra-sensitive virological methods in HIV-infected children receiving early cART in an ongoing project in Cameroon.

Methodology: From 2007 to 2011, 210 HIV-infected infants diagnosed before 7 months of age were included in this study from three urban referral hospitals in Yaounde and Douala. Among them, 147 infants on cART were serologically tested with one ELISA and two rapid HIV tests at a median age of 19.1 months [IQR, 18.2-20.1] and 26 (17.7%) of them were negative. Of the later, whole blood samples were collected from 12 infants and stored at -80°C. HIV level of infection was quantified by measuring total cell associated HIV-DNA in PBMC and plasma HIV-RNA using ultra-sensitive real-time PCRs.

Results: All the 12 children were on cART initiated at a median age of 3.4 months [range, 2.0-7.6] with a median follow up of 47.6 months [range, 21.8-65.1]. They were re-tested serologically at a median age of 50.1 months [range, 26.9-72.7] and 9 of them remained negative. These 9 HIV-seronegative children presented varying profiles of HIV-DNA and HIV-RNA in blood. One child had no replicating virus (HIV-RNA < 24 copies/ml) and no detectable HIV-DNA. Five children had no replicating virus and various low or high HIV-DNA levels (mean 2.35 log copies/10^6 PBMC, range, 2.22-2.59). The last three children had replicating virus (HIV-RNA < 100 copies/ml) with one of them presenting very low viral replication with HIV-RNA at 36 copies/ml and HIV-DNA at 1.6 log copies/10^6 PBMC. HIV-1 Western blot profiles varied from only one p24 antibody in the case of non replicating virus to several antibodies to the Gag and Pol peptides in the case of replicating viruses.

Conclusions: This exploration shows heterogeneous profiles of HIV reservoir in early treated HIV children on cART and seronegative by ELISA. In this preliminary study, two infants had undetectable or a lower blood HIV reservoir. Further immunological investigations are ongoing to better assess the potentiality of HIV control in these infants.

Greater Virologic Control in Infants Initiated On ART Before 6 Months of Age

Stephanie Shiau1, Ashraf Coovadia1, Karl-Gunter Technau2, Renate Strehlau3, Leigh Martens4, Francoise Pinillos2, Elaine J. Abrams1, Louise Kuhn1

1Columbia University, New York, NY, United States; 2University of the Witwatersrand, Johannesburg, South Africa

Background: The recent report of an HIV-infected infant with viral control post-antiretroviral therapy (ART) interruption brings to light the possibility of “functional cure” for infants initiated on ART close to birth. However, there are limited data on the effects of early ART initiation before 6 months of age on the establishment and persistence of viral reservoirs. Here, we examine viral dynamics post-ART initiation by age at initiation.

Methodology: Virological dynamics by age at ART initiation (<6 months vs. 6-24 months) was evaluated in 3 cohorts at Rahima Moosa Mother and Child Hospital in Johannesburg, South Africa. Children in Cohort 1 were initiated on ritonavir-boosted lopinavir (LPV/r)-based ART <24 months of age and randomized to remain on LPV/r or switch to nevirapine after achieving viral suppression. Children 3-5 years of age at enrollment in Cohort 2 were suppressed on LPV/r and randomized to remain on LPV/r or switch to efavirenz. Cohort 3 included children in routine services starting ART <24 months of age.

Results: Of 323 children in Cohort 1, HIV RNA levels were higher pre-ART in 102 children <6 months at ART start vs. 221 children 6-24 months at ART start (75.6 vs. 58.4%, 750,000 copies/ml (cpm); 4.7 vs. 10.7%, <100,000 cpm, p=0.02) but time to and likelihood of achieving viral suppression were similar by age at ART start, suggesting faster trajectories of decline in the younger children. Of 195 children who achieved suppression and were randomized in Cohort 1, mean plasma HIV RNA was 64 cpm in 54 children who started ART <6 months vs. 1502 copies/ml if 6-24 months (NS) after a median of 9 months of ART. Children <6 months at ART start were less likely to fail (>1000 cpm) by 52 weeks post-randomization (p=0.02, adjusted for group). The failures were primarily in those switched to nevirapine. In those retained on LPV/r where failure was rare, children <6 months at ART start were less likely to blip >50 cpm by 52 weeks post-randomization (p=0.04, adjusted for group). Of 300 children in Cohort 2, children <6 months at ART start were more likely to blip >50 cpm than children 6-24 months at ART start (p=0.002). Of 239 children in Cohort 3, children who started ART <6 months were more likely to suppress <1000 cpm by 6 months (54.8%) than those starting 6-12 months (31.4%) or 12-24 months (35.9%) (p=0.03).

Conclusions: Across three separate cohorts, we observed greater virologic control in infants initiating ART <6 months of age. These results are consistent with the notion that early initiation of ART may limit formation of the long-lasting viral reservoir in infants.
925  Early Viral Suppression Improves Neurocognitive Outcomes in HIV-Infected Children
Claudia S. Crowelli1, Yanling Huo2, Katherine Tassopoulos2, Kathleen M. Makele1, Ram Yoge2, Rohan Hazra1, Richard M. Rutstein2, Sharon L. Nichols3, Renee A. Smith2, William J. Muller1, for the IMPAACT 219C Study Team and the PediatricHIV/AIDS Cohort Study  
1Pediatrics, University of Washington, Seattle, WA, United States, 2Epidemiology, Harvard School of Public Health, Boston, MA, United States, 3Northwestern University Feinberg School of Medicine, Chicago, IL, United States, 4National Institute of Child Health and Human Development, Bethesda, MD, United States, 5Children's Hospital of Philadelphia, Philadelphia, PA, United States, 6University of California San Diego, La Jolla, CA, United States, 7University of Illinois at Chicago, Chicago, IL, United States  

Background: Children and adolescents with perinatally-acquired HIV infection (PHIV+) are vulnerable to subtle to severe neurocognitive deficits during development. Initiation of antiretroviral therapy (ART) in infancy is associated with improved longevity; however, it is unclear if timing of ART or a specific ART regimen improves neurocognitive outcomes. Early childhood represents a sensitive period of neurodevelopment and we hypothesized that both early virologic control and use of ART regimens with better central nervous system (CNS) penetration are associated with improved neurocognitive outcomes among school-aged PHIV+ children.  

Methodology: We analyzed data from PHIV+ children from two US-based prospective cohort studies: PHACS AMP (enrolled from 2007 - 2009) and IMPAACT 219C (enrolled from 2000 - 2006) who completed a neurocognitive assessment (WISC-III or WISC-IV) at 6 years of age or older, and who had ≥400 copies/mL obtained 1-6 months apart, and age of viral suppression was defined as the age at first viral load ≤400 copies/mL. CNS penetration effectiveness (CPE) scores were calculated for initial ART regimen and a weighted average CPE score was calculated for each time period of interest. Multivariable general linear regression models were used to evaluate associations of viral suppression and CPE scores with full scale IQ (FSIQ), adjusted for demographic and clinical covariates with p-value < 0.1 from univariable analyses.  

Results: 396 PHIV+ children were included (mean age at time of WISC evaluation=9.6 yrs); 54% were female, 66% Black, 27% Hispanic, and 83% spoke English as the primary language. The percent of children achieving viral suppression increased from 11% by 1 year of age to 41% by age 5. The estimated difference in mean FSIQ (comparing children who were virally suppressed vs. unsuppressed) by each age cutoff was 3.48 at age 1 (p=0.17), 3.43 at age 2 (p=0.10), 2.67 at age 3 (p=0.16), 3.79 at age 4 (p=0.03), and 3.42 at age 5 (p=0.05) after adjusting for age of ART initiation, age at neurocognitive assessment, caregiver education, ethnicity, birth weight and child’s primary language. FSIQ score of initial regimen and weighted average CPE score were not associated with higher FSIQ.  

Conclusions: Virologic suppression during infancy or early childhood is associated with improved neurocognitive outcomes in school-aged PHIV+ children. Although the association attained statistical significance only at ages 4 and 5, the effect size was consistent across all age groups, providing support for early initiation of ART. In contrast, CPE scores showed no significant association with improved neurocognitive outcomes.

926  Early Cytomegalovirus Viraemia and Clinical Outcomes of HIV-Infected Children in the Early ART Era
Nei-yuan Hsiao1, Kennedy Otswome2, Landon Myer3, Ayi Violari2, Diana Gibb3, Ravindre Panchiar2, Abdel Babiker1, Patrick Jean-Phillipes3, Mark Fredric Cotton4  
1Clinical Laboratory Sciences, University of Cape Town, Cape Town, South Africa, 2Perinatal HIV Research Unit, Johannesburg, South Africa, 3Public Health and Family Medicine, University of Cape Town, Cape Town, South Africa, 4Medical Research Council UK, London, United Kingdom, 5National Institute of Allergy and Infectious Diseases, Bethesda, MD, United States, 6Paediatrics and Child Health, Stellenbosch University, Cape Town, South Africa  

Background: Cytomegalovirus (CMV) is an important cofactor for HIV disease progression and is associated with poor outcomes in HIV-infected infants not on antiretroviral therapy (ART). In sub-Saharan Africa, 90% of infants acquire CMV post-natally in their first year of life but its effect on HIV infection among infants on ART is unknown. The purpose of this study was to describe the first year clinical outcomes of young infants with CMV/HIV co-infection who receive antiretroviral therapy.  

Methodology: This study is based on the prospectively assembled cohort from the Children with Early Antiretroviral Therapy (CHER) trial in which 411 infants with CD4 <25% were randomized to immediate or deferred ART and 40 infants with CD4 <25% into a parallel observation group receiving early ART. Early CMV viraemia was determined by Roche COBAS AmpliPrep/COBAS TaqMan CMV PCR (Roche Molecular Diagnostics, Branchburg, New Jersey) using baseline plasma samples. Qualitative and quantitative CMV data was correlated with baseline clinical, immunological and virological parameters and outcomes from the study. Analyses were performed in early and deferred ART strata to determine the confounding effect of early ART on CMV viraemia and outcomes. Outcomes in the first year of life were censored at 40 weeks post enrolment. Immunological failure was defined as a CD4% <25% or <baseline value at the last visit.  

Results: Of 451 infants in the trial, CMV PCR results were available for 363 (median age at enrolment, 7.7 (6.7-9.1) weeks); 89 (25%) were CMV PCR positive at enrolment. Of the children with CMV PCR available, 342 (94%) children initiated ART during follow-up (100%, n=267 in the early treatment group and 78%, n=75 in the deferred treatment group). At enrolment CMV viraemia was associated with breastfeeding exposure (p=0.025), lower CD4 percentage (p=0.001) and higher HIV viral load (p=0.005). Among infants receiving early ART, the proportion reaching a clinical endpoint at one year of life was similar between CMV PCR positive and negative infants (5/75 vs. 8/194; p=0.383) but infants with CMV viraemia had more immunologic failure (12% vs 5%, p=0.049). However no such associations were observed in children in the deferred treatment group (p=0.269) and there was no association between CMV viraemia and death in either group (p=0.862).  

Conclusions: Our study confirms that early CMV viraemia is strongly associated with breastfeeding exposure and poorer immunological status prior to ART initiation. Early ART appears to ameliorate most effects of concurrent CMV infection.
Risk Factors Associated With TB in Children Receiving ART in a South African Multicenter HIV Cohort

Alana T. Brennan1,2, Mharni Maskew2, Kate Schnippel1, Ian Sanne1,2, Lawrence Longi, Matt P. Fox1,2

1Center for Global Health & Development, Boston University, Boston, MA, United States, 2Health Economics and Epidemiology Research Office, Department of Internal Medicine, School of Clinical Medicine, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa

**Background:** Tuberculosis (TB) in children is a direct consequence of adult TB and a good marker of current trends in community transmission. We estimated rates of, and risk factors for, incident TB among HIV-infected children and adolescents receiving antiretroviral treatment (ART) in South Africa.

**Methodology:** Prospective cohort analysis of HIV-infected children <18 years old who initiated ART between April 2004 and May 2011 at one of 12 HIV clinics in Gauteng and Mpumalanga provinces. Duration on ART was categorized as 0-5.9 and >6 months. We used log-binomial regression with a Poisson distribution to determine predictors of TB risk for children <5 and for those 5-18 years, separately, controlling for, gender and current predictors of TB (e.g., age, duration on ART, viral load and hemoglobin). For children <5 we also controlled for CD4 percent and weight-for-age Z-score over time. For children 15-18 we also controlled for CD4 count and body mass index over time.

**Results:** During 2,828 person-years of follow-up, 113 TB cases (diagnosis confirmed by sputum microscopy) occurred among 3,329 pediatric ART patients. This corresponded to an overall incidence rate of 4.0 cases/100 person-years (95% CI: 3.3-4.8). The highest incidence rate was observed in the first 6-months on ART (5.9/100 person-years; 95% CI: 4.7-7.4). Log-binomial models for children <5 years and 5-18 years showed all patients had over a 2-fold increase in the risk of TB in the first 6-months on ART compared to >6-months (Table). Children <5 years of age with a detectable viral load (>400 copies/mL) had a 70% increase in the risk of TB compared to those children who achieved viral load suppression (risk ratio (RR): 1.7; 95% CI: 0.8-3.7) and patients with a low hemoglobin (<10 g/dL) (<5 years - risk ratio (RR): 1.7; 95% CI: 0.6-4.8 and 5-18 years - RR 1.7; 95% CI: 0.8-3.6) were also at increased risk. Amongst children 5-18, those younger in age (5-9.9 vs. ≥10 years-RR 2.4; 95% CI: 1.0-6.0) and patients with low current CD4 count (<100 vs. ≥500 - RR 4.6; 95% CI: 1.5-14.2) were at increased risk of TB.

**Conclusions:** Our results show that younger age and poor immunologic response to treatment are associated with increased risk of TB. Patients are also at increased risk of TB in the first 6-months after initiation onto ART, potentially a result of immune reconstitution inflammatory syndrome (IRIS). Early ART initiation and intensified TB screening at ART initiation may help improve treatment outcomes in younger HIV-positive children and adolescents.

Hepatitis B Treatment Response To TDF in 3TC-Experienced Perinatally HIV-Infected Adolescents
Linda Aurpibul1, Pakagron Lumbiganon2, Pope Kosalaraksa2, Rawiwan Hansudevechakul3, Pawinee Taepsart1, Torsak Bunupuradah1, Thanyawee Puthanakit1, 5, Khuanchai Supparatpinyo1
1Chiang Mai University, Chiang Mai, Thailand, 2Khon Kaen University, Khon Kaen, Thailand, 3Chiang Rai Prachanukroh Regional Hospital, Chiang Rai, Thailand, 4The Netherlands, Australia, Thailand Research Collaboration (HIV-NAT), Bangkok, Thailand, 5Department of Pediatrics, Chulalongkorn University, Bangkok, Thailand

Background: HIV and Hepatitis B (HBV) coinfection is associated with high risk of progression to chronic liver diseases. Loss of the hepatitis B surface (HBsAg) and envelop (HBeAg) antigens are the ultimate goals of treatment. This study aims to determine the incidence rate of seroconversion and kinetics of HBV in perinatally HIV/ HBV coinfected adolescents treating with tenofovir (TDF) and lamivudine (3TC).

Methodology: A prospective multicenter cohort study was conducted in 4 HIV clinics in Thailand. The antiretroviral regimen was modified to include both TDF and 3TC. HBV infected status was monitored by HBsAg and HBeAg levels using semiquantitative method based on the ratio of sample relative light units to a control cut-off (S/CO), hepatitis e antibody (anti-HBe) and HBV DNA level. Treatment response of HBV infection and serum alanine aminotransferase (ALT) were captured at 12, 24, and 48 weeks. Hepatic flare was defined as ALT > 5 times of upper limit of normal.

Results: From March-October 2012, 12 perinatally HBV/HIV infected adolescents with median age of 17.6 (range 14.2-21.9) years, and mean body mass index of 19.0 (± 2.4) kg/m2 were enrolled. Their mean CD4 lymphocyte count was 678 (± 183) cells/mm3; 83% had HIV RNA level < 40 copies/mL. At week 12, 24, and 48 follow-up, significant decreases in HBV DNA and HBeAg levels from baseline value were observed. The median HBV DNA reduction from baseline were 3.3 (range 0-8.2) and 7.2 (range 1.2-8.2) log10 copies/mL at week 12 and 24, respectively. At the end of follow-up, HBV DNA level were < 2.0 log10 copies/mL in 77%, and < 20 copies/mL in 33% of cases. Only one case developed HBsAg seroconversion at week 48; however, there was a persistent low-level HBeAg titer and anti-HBe remained negative. No case experienced hepatic flare.

Conclusions: TDF suppressed viral replication in most HBV/HIV co-infected adolescents who had previously been exposed to 3TC, at least half of whom had pre-existing HBV-3TC associated resistance. Hepatic flare was not evidenced in this population. Long term follow-up study on efficacy of HBV combination therapy with TDF/3TC as well as liver outcome among HBV/HIV coinfected adolescents is required.

T-Cell Senescence and CMV Positivity and Viremia Status in Perinatally HIV-Infected Children
Suad Kapetanovic1, Lisa Aaron2, Grace Montepiedra1, Andrea Kovacs3
1National Institute of Mental Health, National Institutes of Health, Bethesda, MD, United States, 2School of Public Health, Harvard University, Boston, MA, United States, 3Keck School of Medicine, University of Southern California, Los Angeles, CA, United States

Background: We examined longitudinal effects of cytomegalovirus (CMV) co-infection and viremia on CD4 and CD8 T cell subsets in a cohort of treated perinatally HIV infected (PHIV+) children with severe disease.

Methodology: Pediatric AIDS Clinical Trials Group protocol 366 (P366) was an open-label, multicenter 96 week study where PHIV+ children received 2-4 new drugs (Table) depending on their previous antiretroviral therapy (ART). The analysis included 107 P366 enrollees ≥1 year old with available T cell subset data and baseline stored plasma samples. CMV IgG and CMV DNA testing was performed on stored plasma specimens. Linear mixed models assessed associations between baseline CMV status and percentages of CD4 and CD8 T cell phenotypes weeks 0, 12, 20, and 40, adjusting for potential covariates (Table). Interaction terms between CMV status and week were added to the models.
Results: Average participant age was 7 years, 58% were Black Non-Hispanic, 55% males; at entry, 98% were on ART, 37% in CDC category C. Forty-one % were VL responders (Table) at week 16 of the new regimen; 19% partial responders; 26% non-responders. Fourteen % had detectable CMV DNA ("CMV+ viremic"); 49% were IgG positive or had a positive baseline CMV blood or urine test result but no detectable CMV DNA ("CMV+ non-viremic"); 37% were IgG negative and had no recorded CMV+ result ("CMV-negative"). The percentages of four CD8 phenotypes (CD8+CD62L-CD45RA+; CD8+CD62L+CD45RA-; CD8+CD95+CD28-; CD8+CD95-CD28+) were significantly associated with baseline CMV status in adjusted models. The trends over time differed by CMV category and/or treatment arm, with significant week*CMV status and/or week*treatment arm interactions. (Table) None of the CD4 phenotype percentages, activated CD8 phenotypes percentages, CD8+CD62L+CD45RA-%, CD8+CD62L-CD45RA-%, CD8+CD95+CD28-%, or CD8+CD95-CD28-% differed by CMV status in multivariate models.

Conclusions: In PHIV+ children with severe disease, changes in percentages of CD8+CD62L+CD45RA+, CD8+CD95+CD28- and CD8+CD95-CD28+ after switching to new multi-drug ART regimen depended on the children's CMV positivity and viremia status and treatment arm; the effect was independent of VL treatment response. Combined, these findings suggest an independent role of CMV co-infection in alterations in CD8 T cell functional recovery following switch to a multi-drug ART regimen in PHIV+ children.

Background: With improved pediatric antiretroviral therapy (ART) access, perinatally HIV-infected children are now surviving into late childhood and adolescence-limiting settings. There are limited data on the characteristics and outcomes of these children.

Methodology: We included all children with presumed perinatal HIV infection (defined as ART initiation at age <9.5 years without documented non-perinatal acquisition of HIV) and remaining in care beyond 10 years of age at 10 IeDEA-SA sites in 3 countries (Malawi, South Africa, Zimbabwe) from 2000 to 2012. We described characteristics at ART initiation, at entry into the analysis at age 10 years and at the end of follow-up. The probabilities of death, loss to follow-up (LTFU) (no visit for 270 days before database closure) and transfer out between 10 and 13 years of age were determined using the Kaplan-Meier estimator.

Results: Among 2,161 children included, median (interquartile range [IQR]) age at ART initiation was 7.3 (5.8-8.5) years, with many children having advanced clinical or immunologic disease at ART start (84% WHO III/IV Clinical Stage; 70% WHO-defined severe immune suppression) (Table). Most children initiated a regimen of stavudine+lamivudine with either efavirenz (77%) or nevirapine (10%), while 13% initiated other regimens. At age 10 years, after a median (IQR) of 33 (18-50) months on ART, few children had severe disease; only 3% had CD4<200 and 5% weight-for-age z-score <-3, with HIV-RNA <400 copies/ml in 82%. The probabilities (95% confidence interval [CI]) of death, LTFU and transfer out by age 13 years were 0.8% (0.5-1.5); 7.3% (5.9-9.1); and 30.4% (28.0-32.9) respectively. Among the 2,147 surviving children, 97% had CD4 >200 cells/μl and 77% had HIV-RNA <400 copies/ml at the end of follow-up.

Conclusions: Mortality on ART is low during early adolescence in perinatally HIV-infected children who survive to 10 years of age. The majority of those in care are virologically suppressed with CD4 >200 cells/μl. However, nearly one-third of children transfer out of pediatric care during early adolescence, and the outcomes of these children require attention.

Table: Characteristics of children with presumed perinatal HIV infection who survive to at least 10 years of age. Characteristics are described at ART initiation, at age 10 years, and at last follow-up.

931 Greater Early CD4 Responses To cART Initiation Not Maintained for Non-Perinatal Youth

Allison Agwu1, Guy Mahiane2, Bareng A. S. Nonyane3, Keri Althoff4, Baligh Yehia5, Stephen Berry6, Richard Rutstein7, Kelly A. Gebo6, for the HIV Research Network

1Pediatrics & Medicine, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 2Department of International Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, 3Department of Medicine, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 4Department of Pediatrics, Children’s Hospital of Philadelphia, Philadelphia, PA, United States, 5Department of Medicine, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 6Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States, 7Department of Pediatrics, Children’s Hospital of Philadelphia, Philadelphia, PA, United States

Background: Non-perinatally HIV (nPHIV)-infected youth are more likely to have delayed initiation of combination antiretroviral therapy (cART) and have higher nonadherence to cART than adults. Youth have residual thymic tissue and potentially greater capacity for immune reconstitution than adults. We compared CD4 responses to cART between nPHIV-infected youth (12-24 years-old) and adults (≥25-44 years-old).

Methodology: Retrospective analysis of nPHIV-infected cART-naïve individuals 12-44 years-old, who initiated their first cART between 2008 and 2011 at clinical sites in the HIV Research Network. Age was limited to <45 years to avoid the impact of co-morbidities with increasing age. A generalized linear mixed model assessed the association between the repeated outcomes of CD4 gain≥100 cells/mm3 at each visit after cART initiation and age category (12-24, 25-34, 35-44 years). The model accounted for random variation within each participant and between sites, and adjusted for gender, race/ethnicity, HIV acquisition risk, baseline CD4 and log10HAV-1 RNA, virologic suppression (<2.6 log), and cART duration.

Results: Of 3,326 individuals (523 youth, 2803 adults) included, a greater proportion of youth vs. adults were male (83% vs. 74%, p<0.001), had MSM HIV acquisition (72% vs. 50%, p<0.001), and baseline CD4 200-349 cells/mm3 (40% vs. 31%, p<0.001). At 24 weeks after cART initiation, 45% vs. 39% (p=0.04) of youth vs. adults attained CD4 gain≥100 cells/mm3; subsequently, the proportion fell below that of adults. Virologic suppression rates for youth vs. adults were 74% vs. 73% (24-weeks) and 73% vs. 77% (48-weeks), p=0.3 (both). When adjusting for gender and race/ethnicity alone the adjusted odds ratio (AOR) of CD4 gain≥100 cells/mm3 was 1.2 (95% CI 0.93-1.6) and 1.3 (95% CI 1.0-1.6) for those 12-24 and 25-34 vs. 35-44 years; however, this effect was non-significant after adjusting for other potential confounders (See table).

Conclusions: With virologic suppression, youth achieved CD4 gains ≥100 cells/mm3 earlier than adults, however, this trajectory was not sustained. CART initiation for youth should not be delayed with the expectation that residual capacity for immune reconstitution will result in greater CD4 responses. Maintaining virologic suppression is the most critical factor to enhancing CD4 outcomes, especially for youth who traditionally have higher nonadherence rates.

932 Parental Absence From Clinic Predicts Virologic Failure in Adolescents in Botswana

Elizabeth Lowenthal1,2, Tafireyi Marukutira3, Ontibile Tshume3, Jennifer Chapman2, Tebo Dipotso2, Omphile Lepadisi4, Keboletse Mokete4, Jean Nachega5, Gabriel Anawani1, Robert Gross1, 2

1Pediatrics and Epidemiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States, 2Children’s Hospital of Philadelphia, Philadelphia, PA, United States, 3Botswana-Baylor Children’s Clinical Centre of Excellence, Gaborone, Botswana, 4Sfelenzobisch University, Cape Town, South Africa, 5University of Pittsburgh, Pittsburgh, PA, United States, 6Medicine and Epidemiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States, 7Botswana-UPenn Partnership, Gaborone, Botswana

Background: HIV-infected adolescents have higher rates of non-adherence and virologic failure than younger children and adults. Adolescents may attend clinic with or without an adult caregiver (parent). We hypothesized that routine clinic attendance without a parent would increase the risk of treatment failure, particularly in younger adolescents.

Methodology: We conducted a prospective cohort study of HIV-infected adolescents (age 10-19) on ART at the Botswana-Baylor Children’s Clinical Centre of Excellence in Gaborone, Botswana. We calculated the relative risk of virologic failure (VL≥400cpm) between those with/without a parent present at the 3 month and 6 month study visits. We evaluated for confounding by sex, orphan status (death of either parent), and time on treatment using multivariable logistic regression. The likelihood of failure with increasing age was calculated using linear regression for those with and without a parent present at 3 months. We tested for interaction between age and parent presence using linear regression.
Results: We enrolled 298 adolescents, median age 13.3 years (IQR 11.8-15.6), 52% female, median time on treatment 7.5 years (IQR 5.4-8.8). Detectable viral load was present in 35 adolescents (12%) at month 3 and 15(9%) adolescents at month 6. Absence of a caregiver conferred a relative risk of 2.5 (95% CI 1.4-4.6) of failure at month 3 and 3.4 (95% CI 1.3-9.2) at month 6. There was no confounding. For each year of age, the risk of failure increased [6% per year (95% CI: 2-10%)] among those without a parent present, but not for those with a parent present [0.3% per year (95% CI: -0.8%-0.8%)]. The p-value for the interaction between age and parent presence was <0.001 (see Figure).

Conclusions: Absence of a parent conferred a higher risk of virologic failure. Older adolescents without a parent present in clinic were at highest risk. Interventions to identify potentially supportive caregivers and strengthen the adolescent/parent dyad might lower the adolescents’ risk of treatment failure. Particular attention should be paid to older adolescents who attend clinic alone.

933LB ART De-Intensification to ATVr Monotherapy in Adolescents Sustains CD4 and Activation Responses

Bret J. Rudy1, Bill Kapogiannis2, Craig Wilson3, Allison Agwu4, Maureen Goodenow5, Carol Worell6, John W. Seasman7, Sue X. Li8, James Bethel9, Kathleen Squires1

1Pediatrics, NYU School of Medicine, New York, NY, United States, 2Pediatrics, National Institutes of Health, Bethesda, MD, United States, 3University of Alabama at Birmingham, Birmingham, AL, United States, 4Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 5University of Florida College of Medicine, Gainesville, FL, United States, 6Maternal and Pediatric Infectious Disease Branch, National Institutes of Health, Bethesda, MD, United States, 7Duke University Medical Center, Durham, NC, United States, 8Westat, Rockville, MD, United States, 9Internal Medicine/Infectious Diseases, Thomas Jefferson University, Philadelphia, PA, United States

Background: Adolescents and young adults infected with HIV face a lifetime of antiretroviral therapy (ART). Toxicities to antiretroviral therapy persist, including negative effects on bone renal function, and lipids; thus, limiting ARV exposure may still be of benefit. Assessing the impact of such interventions requires an understanding of their influence on viral suppression and T cell reconstitution and immune activation.

Methodology: 75 subjects, ages 18-24, with CD4 T cells > 350 were started on FTC/TDF/ATVr as part of a randomized, unblended trial of therapy de-intensification. Subjects who maintained an HIV viral load (VL) < 100 copies from weeks 24 through 48 were de-intensified to ATVr monotherapy at week 52 and to week 152. Subjects failed de-intensification for a confirmed VL > 400 copies or confirmed CD4 drop of > 30% from the average of the two peak values. Markers of T lymphocyte differentiation/activation were analyzed by multi-parameter LSR II flow cytometry to define naïve, central memory (CM), and effector memory (EM) CD45RA and CD45RO subpopulations. Slopes of changes in T cell subsets and T cell activation from weeks 48 to 152 were estimated by a mixed effects model using a t-test to test whether mean slopes equaled zero.

Results: 49 of 75 subjects met criteria at week 48 of ART for de-intensification. 25 of 49 (51%) remained suppressed on monotherapy to week 152. Total CD4 gains during ART persisted during de-intensification with ongoing significant increases in naïve and CM (p=0.0167 and 0.0186, respectively) and a decrease in EMRA (p=0.0007) subsets from weeks 48 to 152. No significant changes occurred during monotherapy in any CD8 subpopulations. The significant increases in CD28 expression and decreases in CD38 and HLADR expression on CD8 subpopulations during ART were maintained during de-intensification to monotherapy without any significant increases to from week 48 through week 152. In 19 subjects failing de-intensification due to rebound virus, none demonstrated ATV resistance. Adherence was similar in those failing monotherapy up to the point of failure compared to those maintaining suppression.

Conclusions: In subjects treated with ART with CD4> 350, de-intensification to monotherapy with ATVr following 48 weeks of ART is effective in maintaining naïve and CM CD4 T cell reconstitution. No ATV resistance was noted in subjects with confirmed virologic failure. No increases in immune activation were found in those maintaining viral suppression. This strategy merits further investigation to determine its appropriateness selected populations.

934 Factors Associated With Successful Retention Among Non-Perinatally HIV-Infected Youth

Charles Farmer1, Baligh Yehia2, Richard Rutstein3, Stephen Berry4, Kelly Gebo5, Allison Agwu6, for the HIV Research Network

1Johns Hopkins University School of Medicine, Baltimore, MD, United States, 2Division of General Pediatrics, Children’s Hospital of Philadelphia, Philadelphia, PA, United States, 3Department of Medicine, Division of Infectious Diseases, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States, 4Division of Infectious Diseases, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States, 5Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States, 6Departments of Pediatrics & Medicine, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, MD, United States

Background: The incidence of HIV infection continues to increase among youth infected through risk behaviors, who often face individual and structural barriers to retention in care. Retention is critical for HIV treatment success, and is associated with positive clinical outcomes and a decrease in HIV transmission risk behaviors. We evaluated the clinical and demographic characteristics of non-perinatally HIV (nPHIV)-infected youth associated with retention one year after initiating care.

Abstract Listing
**Methodology:** The study was a retrospective analysis of treatment-naïve, nPHIV-infected youth (ages 12-24 years) presenting for care at 16 U.S. HIV Clinical Sites within the HIV Research Network (HVRN) between 2002 and 2008. Eligible patients were included if they had at least one CD4 value and an outpatient visit in the first four months after initiating care. The primary outcome, retention, was defined by the HRSA In+Care Campaign measure of having one medical visit during each of the three successive 4-month periods in the first year. Multivariate logistic regression was used to determine associations with retention and patient factors (age, gender, race/ethnicity, HIV transmission risk, insurance, antiretroviral therapy use (cART) use), adjusting for clinic site.

**Results:** Of 1,160 nPHIV-infected youth, 74% were male, 61% were Black, 58% had MSM-related HIV acquisition, and 45% were retained in care during their first year of care. Retention in the first year of care was independently associated with use of cART (adjusted odds ratio 3.47, 95% confidence interval 2.57-4.67), Hispanic ethnicity (1.66, 1.08-2.56), MSM-related HIV transmission (1.59, 1.07-2.36), and receiving care at a pediatric site (5.37, 3.20-9.01). Injection drug use transmission risk (vs. heterosexual risk) was associated with poor retention in care (0.43, 0.19-0.99).

**Conclusions:** The high proportion of newly enrolled nPHIV-infected youth that were not retained in care within one year after initiating care is alarming. Our study indicates specific subgroups that are at risk of not being retained in care and highlights factors that may be associated with improved retention. These findings may inform programs to optimize retention of nPHIV-infected youth.

936 Irreversible Inactivation and Breakdown of HIV-1 With Env-gp120 Targeting Peptide Triazole Thiolis

Arangassery Rosemary Bastian1, Lauren D. Bailey1, Diogo R. D. Moreira1, Kevin Freedman1, Karyn McFadden1, Caitlin Duffy1, Ali Emileh1, Jeffrey Jacobson1, James A. Hoxie1, Irwin Chalken2
1Biomedical Engineering and Sciences, Drexel University, Philadelphia, PA, United States, 2Biotechnology and Molecular Biology, Drexel University, Philadelphia, PA, United States

Background: Infection of HIV-1 into host cells remains a compelling target for developing agents to prevent infection. This step is mediated by a sequence of interactions of a trimeric gp120/gp41 virus envelope (Env) protein complex with host cells. Peptide triazoles, a class of entry inhibitors have shown to bind to gp120 with close to nanomolar affinity, to suppress protein ligand interactions of gp120 with CD4 and co-receptor binding sites, and to inhibit cell infection by a broad range of virus subtypes. We found that sulfhydryl-containing peptide triazoles (PT-SH), irreversibly disrupts cell-free virions, leading to virus core release. We seek to understand the mechanism of this cell-free virolysis. We hypothesize that the PT-SH hijacks the viral fusion mechanism prior to cell fusion and leads to transient pore formation resulting in irreversible virolysis.

Methodology: The peptide triazoles (PTs) were synthesized using solid phase Fmoc chemistry with click conjugation. The PTs included KR13 (PT-SH); KR13b (KR13 with the thiol blocked); KR13s (containing a scrambled KR13 sequence), and the parent PT, HNG156, with no free thiol. Infection inhibition by PTs were compared using a single-round infection assay using lab synthesized pseudoviruses. Release of Env gp120 and nucleocapsid protein p24 from the PT treated virions were tested by Western blot and ELISA respectively. The fixed residual virion was tested for gp41 recognition by direct ELISA using antibodies 2F5 and 4E10 and morphological analysis using transmission electron microscopy. To compare the relationship of KR13 induced cell-free virolysis and virus-cell entry, we examined the effect of T20 on the inhibition of KR13 induced virolysis.

Results: The PTs with active pharmacophore (KR13, HNG156 and KR13b) all inhibit viral infection and induce gp120 shedding; uniquely only KR13 induced release of the core protein p24. Viral inactivation and gp120 shedding had a similar time-dependence, while p24 release lagged temporally. The resulting virions lacked an organized capsid and the gp41 on the virions were antigenically active against neutralizing antibodies, 2F5 and 4E10. Viral lysis was completely inhibited by T20, which blocks formation of the gp41 6-helix bundle during membrane fusion.

Conclusions: Our data are consistent with a model in which PT-SH triggers physiologic structural changes in the HIV-1 Env including the 6 helix bundle formation that is typically associated with viral fusion and entry. The potency and specific activity of this novel compound and its ability to inactivate virions prior to target cell engagement suggest that KR13 could be highly effective as a microbicide in HIV prevention and transmission as well as a probe to understand biochemical signals required for virus-cell fusion.

937 Labyrinthopeptin A1 Demonstrates Potent and Dual Anti-HSV and Anti-HIV Activity

Geoffrey Férré1, Mariya Petrova1, Graciela Andreí, Robert Snoeck1, Jos Vanderheyden1, Roderich Süßmuth2, Mark Brünnstrup1, Dominique Schols1
1Rega Institute, Leuven, Belgium, 2Centre of Microbial and Plant Genetics, Leuven, Belgium

Background: It has been shown that genital lesions and altered innate mucosal immunity caused by HSV-2 are important cofactors to increase the rate of HIV transmission and infection. Therefore, a product that inhibits both HIV and HSV would have potential benefits in the prophylaxis against these sexually transmitted viruses. Lantibiotics are peptides that contain the noncanonical amino acid lanthionine. The labyrinthopeptin A1 (LabyA1) is a prototype peptide of a novel class of carboxylic lantibiotics. Here, we extensively evaluated LabyA1 for its broad-spectrum activity against HIV and HSV and its microbicidal application.

Methodology: Replication of HIV-1, HIV-2 and drug (such as tenofovir, maraviroc, raltegravir, saquinavir)-resistant viruses were measured in CD4+ T cell lines and in peripheral blood mononuclear cells (PBMCs) by the colorimetric MTS method and p24/p27 ELISAs. LabyA1 was also tested against HSV-1, HSV-2 strains, isolates and HSV-resistant viruses (such as acyclovir) in different cell types. It was tested alone and in combination with various other classes of anti-HIV/HSV drugs. EC50 values and potential synergy levels were calculated using CalcuSyn software based on the median effect principle. Potential cellular side-effects, cytokine induction, toxicity and growth inhibitions were measured by flow cytometry and multiplex immunoassays.

Results: LabyA1 exhibited a consistent and broad anti-HIV activity (EC50: 0.70 - 3.3 μM) and anti-HSV activity (EC50: 0.29 - 2.8 μM) in cell cultures. LabyA1 also inhibited viral cell-cell transmission between persistently HIV-infected T cells and uninfected CD4+ T cells (EC50: 2.5 μM) and inhibited the transmission of HIV captured by DC-SIGN+ cells to uninfected CD4+ T cells (EC50: 4.1 μM). In depth studies revealed that LabyA1 behaves as a novel type of viral entry inhibitor. LabyA1 also demonstrated additive to synergistic effects in its anti-HIV-1 and anti-HSV-2 activity with anti(retro)viral drugs in dual combinations such as tenofovir, acyclovir, saquinavir, raltegravir and enfuvirtide. LabyA1 was equally active against all drug-resistant HIV and HSV strains compared to wild-type viruses. It also did not induce any inflammatory cytokines/chemokines in PBMC and vaginal epithelial cells, it did not induce cellular activation markers and did not affect the growth of more than 10 different vaginal Lactobacillus populations that were evaluated.

Conclusions: LabyA1 has profound antiviral activity against HIV and HSV. Based on the lack of toxicity on the vaginal Lactobacillus strains and its synergistic/additive profile in combination with all approved anti(retro)virals, it deserves further attention as a potential microbicide candidate in the prevention of sexually transmitted (HIV/HSV) diseases.
938  GSK1265744 Demonstrates Robust In Vitro Activity Against Various Clades of HIV-1
Sharon L. Karmon1, Hiroshi Mohri1, William Spreen2, Zhi Hong2, David Ho2, Martin Markowitz1
1Aaron Diamond AIDS Research Center, an affiliate of The Rockefeller University, New York, NY, United States, 2GlaxoSmithKline, Research Triangle Park, NC, United States

**Background:** GSK1265744 (744) is a potent integrase strand-transfer inhibitor formulated as a long acting (LA) injection; 744LA is being tested preclinically as pre-exposure prophylaxis (PrEP) in the rhesus macaque/SHIV162P3 model. To confirm the promise of 744LA as PrEP we analyzed the susceptibility of recombinant viruses containing patient-derived HIV-1 integrase from various recently acquired HIV-1 clades to 744 in vitro.

**Methodology:** We tested the susceptibility of 20 recombinant viruses with patient-derived integrase from various clades (A1, AE, B, C and D) to GSK744. The integrase genes were amplified and recombined into an HXB2-derived proviral DNA clone, and pseudotyped viral stocks were generated by cotransfecting these proviral DNAs and pCI-VSV-G into HEK293T cells. We employed a single-cycle infectivity assay to determine the relative 50% and 90% inhibitory concentrations (IC50 and IC90) of 744 against our pseudovirus panel.

**Results:** Each virus showed a 744 IC50 and IC90 comparable to the wild-type control, as measured by fold change (FC) versus wild-type (Table 1), with an overall median IC50 FC of 0.88 (range = 0.12-1.38). Two viruses with integrase resistance mutations to raltegravir were also tested: one with G140S and Q148H amino acid changes, and the other with mutations E92Q and N155H. These viruses had significant resistance to raltegravir in this assay (IC50 FC of 5308 and 441, respectively), but only modest increases in IC50 to 744 (FC of 11 and 4).

**Conclusions:** GSK1265744 exhibited broad in vitro activity against integrase from multiple clades of HIV-1 in newly-infected patients. The data support the potential for 744LA as a next-generation PrEP agent.

939  Does Tenofovir Gel Alter HIV Disease Progression in CAPRISA 004 Trial Seroconvertors?
Nigel J. Garrett1, Lise Werner1, Nkashmee Naicker1, Thabile Mthembu1, Vivek Naranbhai1, Sengziezi Sibeko1, Natasha Samsunder1, Carolyn Williamson2, Quarraisha Abdool Karim1,3, Salim Abdool Karim1,3
1CAPRISA, Durban, South Africa, 2Institute of Infectious Diseases and Molecular Medicine & the Division of Medical Virology, Cape Town, South Africa, 3Columbia University, New York City, NY, United States

**Background:** While topical and oral antiretroviral pre-exposure prophylaxis (PrEP) prevent HIV acquisition, it is not known if they also alter HIV disease progression in individuals acquiring HIV. This study assesses whether tenofovir (TFV) gel impacted disease progression among women who acquired HIV during the CAPRISA 004 microbicide trial.

**Methodology:** CAPRISA 004 trial seroconvertors were followed until antiretroviral therapy (ART) initiation. Disease progression was assessed by viral load (VL) and CD4 counts. Since a CD4 count of 350 cells/μl is the threshold for ART initiating, time to this event was used as principal measure for disease progression. Linear mixed models were fitted to all available CD4 count and VL measurements in the first 2 years of infection. Participants reaching the CD4 count threshold were compared by log rank test.

**Results:** Eighty-three women, median age 22 years (IQR 21-25), who acquired HIV infection during CAPRISA 004 (32 assigned to TFV gel) contributed 296 women years of ART naïve follow up. Median VL at median 2 weeks post infection was 4.74 (IQR 3.97-5.37) and 4.45 (IQR 3.56-5.17) log copies/ml in women from the TFV and placebo arms, p=0.189. Corresponding 12 months post infection median VLs were 4.24 (IQR 3.74-4.77) and 3.70 (IQR 2.60-4.66) log copies/ml, p=0.016. After adjusting for age, sexual behaviour, contraceptive use and presence of sexually transmitted infections in the first 3 months post infection, the overall mean VL was 4.07 (SE=0.48) and 3.58 (SE=0.47) log copies/ml in women assigned to TFV and placebo, p=0.015. Corresponding mean CD4 counts were 571 (SE=119.44) and 620 cells/μl (SE=115.59), p=0.326. Seven placebo arm (15.6%) and one TFV arm (3.3%) women had VLs <400 copies/ml at 1 year post infection, p=0.134. No antiretroviral drugs were detected in their plasma. HLA haplotypes B57/B5801 were present in 13 women (6 TFV, 7 placebo). Adjusting for these haplotypes, mean VL for TFV and placebo were 4.49 log copies/ml (SE=0.20) and 3.97 (SE=0.19), p=0.011. Among women assigned to TFV gel, the mean VLs were 4.53 (SE=0.27) and 4.54 (SE=0.30) log copies/ml in women with detectable versus undetectable TFV levels in the genital tract, p=0.966. A total of 32 (38.6%) women reached a CD4 count <350 cells/μl at median 9.4 months post infection, 13 (40.6%) from the TFV and 19 (37.3%) from the placebo arms, p=0.786.
Conclusions: TFV gel had no impact on post infection CD4 counts and did not accelerate disease progression among women who acquired HIV in the CAPRISA 004 trial. The difference in HIV VL remains to be fully explained although a large proportion of placebo arm women had very low VL at 1 year post infection. TFV gel use as PrEP does not appear to adversely affect disease progression in women acquiring HIV.

940 Efficacy of Vaginal Gel Containing Tenofovir and Emtricitabine Against Rectal SHIV Transmission

Charles W. Dobard, Natalia Makarova, Rolieria West, Andrew Taylor, Chuong Dinh, Amy Martin, James Mitchell, Debra Hanson, Chou-Pong Pau, Walid Heneine

1HIV and prevention, Centers for Disease Control, atlanta, GA, United States, 2Quantitative Sciences and Data Management Branch, Centers for Disease Control, atlanta, GA, United States

Background: Vaginal gels containing tenofovir (TFV) and Emtricitabine (FTC) dose vaginal tissues with high concentrations of drugs and fully protect macaques from vaginal SHIV infection. These vaginal gels also result in drug distribution to the rectum, raising the possibility of bi-compartmental protection. Here, we used pigtail macaques to study the kinetics of rectal drug exposures following vaginal dosing with TFV/FTC gel and assess efficacy against rectal SHIV infection.

Methodology: Six pigtail macaques were administered hydroxyethyl cellulose gel (3 mL) containing 5% FTC and 1% TFV vaginally once-weekly for 3 weeks. Kinetics of rectal drug distribution were determined by measuring drug levels in rectal secretions at 0.5, 2, and 6h. To evaluate efficacy, macaques were challenged rectally with low-dose SHIV 1030 30 minutes after intravaginal dosing with either HEC placebo (n=6) or 5% FTC/1% TFV (n=6) gel. Animals were challenged twice-weekly for up to 8 weeks. Infection was monitored by serology and plasma virus load by using RT-PCR.

Results: The median AUC of FTC and TFV in rectal secretions following vaginal gel dosing was 330 ug/hr/ml (range: 210 - 700) and 113 ug/hr/ml (range: 7.6 - 270), respectively. Median FTC and TFV concentrations in rectal secretions at 0.5, 2, and 6h were 0.54 and 0.047, 31.9 and 14.3, and 41.1 and 18.6 ug/ml, respectively. All macaques receiving vaginal placebo gel became infected after a median of 3.5 challenges. All 6 macaques administered vaginal FTC/TFV gel were infected after a median of 10 rectal challenges. The infection probability was not significantly different between control (0.18 [95% CL 0.07, 0.35]) and treated animals (0.12 [95% CL 0.03, 0.21]) (Fisher’s exact p=0.53).

Conclusions: Both FTC and TFV rapidly distributed to rectal tissues following vaginal gel dosing at concentrations 2-3 logs lower than those in vaginal tissues. These rectal drug levels were not sufficient to maintain the high efficacy observed vaginally. Further studies are warranted to determine whether improved vaginal gel formulations or drug combinations can be utilized to increase rectal drug exposures and efficacy.

941LB GSK1265744 Long-Acting Protects Macaques Against Repeated High-Dose Intravaginal Challenges

1Aaron Diamond AIDS Research Center, New York, NY, United States, 2GlaxoSmithKline, Research Triangle Park, NC, United States, 3Tulane National Primate Research Center, Covington, LA, United States

Background: GSK1265744 (GSK744) long-acting (LA) is a strand-transfer inhibitor of HIV/SIV integrase (InSTI) formulated as a 200 mg/mL injectable nanoparticle suspension. GSK744 LA is an effective pre-exposure prophylaxis (PrEP) agent against repeated low-dose intrarectal SHIV exposures in male rhesus macaques. This study was performed to evaluate the effectiveness of GSK744 LA as PrEP against high-dose intravaginal SHIV challenges.

Methodology: Twelve female rhesus macaques were injected intramuscularly (IM) with 30 mg Depo Provera on weeks -3 and 2 to synchronize the menstrual cycle and thin the cervicovaginal epithelium. Eight macaques were injected IM with 50 mg/kg GSK744 LA on weeks 0 and 4, and 4 macaques remained untreated as controls. All 12 macaques were challenged intravaginally with high dose SHIV162P3 (300 TCID50) on week 1. GSK744 LA-treated macaques were further challenged with the same dose of virus at weeks 5 and 7. Infection status was monitored weekly by quantifying viral RNA (vRNA) in plasma. Plasma GSK744 concentrations were measured weekly by HPLC-MS/MS.

Results: All 4 control macaques became infected after a single high-dose challenge. Plasma vRNA was detected in control macaques 1 to 2 weeks after the first challenge (see figure). Of the 8 GSK744 LA-treated macaques, six remained aviremic through week 24 (p=0.0003, log-rank test). In the two GSK744 LA-treated macaques that became infected, plasma vRNA was detected 3 and 7 weeks after the last challenge. Consensus sequencing of the integrase-coding region showed breakthrough infections were initiated with wild-type virus, and no drug resistant mutation was identified. Drug concentrations at the time of vRNA detection were 0.15 or 0.37 μg/mL GSK744, respectively. Further investigation of the protective mechanism versus route of infection and virus titers may be warranted. In the aviremic macaques, GSK744 plasma levels fell below 1X protein-adjusted IC90 between weeks 9 and 16, suggesting late viral breakthrough is unlikely.

Conclusions: Using a stringent high-dose intravaginal SHIV challenge model where all control macaques became infected after one challenge, GSK744 LA administration protected 6 of 8 female macaques against three challenges. These results support further clinical development of GSK744 LA as PrEP in women at high risk for HIV-1 infection.
**SHIV Infection Risk After Rectal Application of a Highly Osmolar Personal Lubricant**

Sundaram A. Vishwanathan, Monica Morris, Charles Rose, Richard J. Wolitski, Leecresia Jenkins, Shanon Ellis, Michael Hendry, Janet M. McNicholl, Ellen N. Kersh

**Background:** Personal lubricant use is common for anal sex. Some water-based products with high osmolality and low pH can damage rectal tissues. Additionally, the preservative polyquaternium 15 (PQ15) can enhance HIV replication in vitro. This has raised concerns that lubricants with such properties may increase STD/HIV infection risk, although in-vivo evidence is scarce. In 2012, the WHO issued an interim advisory note to limit use of rectal lubricant formulations >1,200 mOsm/kg, with pH < 5.5, and containing PQ15. We use an animal model to test the hypothesis that a widely used, highly osmolar (>8,000 mOsm/kg), water-based lubricant with pH of 4.4, and containing PQ15 increases risk for HIV infection.

**Methodology:** To determine susceptibility to infection, we compared virus doses needed for infection in 20 lubricant- or control treated cynomolgus macaques. The macaques received six rectal, non-traumatic applications of lubricant or buffered saline during 3 weeks, followed by rectal virus exposures 30 minutes after the last lubricant application with escalating doses (1.25–25,000 tissue culture infectious doses [TCID-50] of SHIV SF162P3). We had previously observed an increase in rectal pro-inflammatory cytokines and epithelial tissue peeling after application of the lubricant. Uninfected macaques were rested for at least 6 weeks, and then re-exposed to higher doses until 47 exposures and 15 infections (controls=7, lubricant=8) had occurred. We calculated and compared animal infectious doses (AID-50) by modeling HIV infection as a function of the log10 TCID-50 using logistic regression.

**Results:** The estimated AID-50 was 2,990 TCID-50 (95% confidence interval [CI]: 200, 44750) in lubricant-treated macaques and 1,808 (CI: 728, 4495) in controls. The estimated AID-50 ratio of lubricant-treated macaques to controls of 1.65 (CI: 0.15, 17.9) was not statistically significant different (p = 0.72).

**Conclusions:** The tested lubricant did not increase susceptibility to infection. This indicates that neither the type and extent of inflammation induced by this lubricant, nor the presence of PQ15, affected infection risk in this model. Additional approaches could further clarify the effects of lubricant use on HIV risk by evaluating other products, vaginal and penile use, and by analyzing potential beneficial lubricant effects stemming from reduced condom breakage and tissue trauma during sex.

**Identifying and Reducing HIV Risk**

**943 Controlled Trial of an Internet-Based Risk Reduction Intervention in HIV+ Men Who Have Sex With Men**

Joel Milam, Sonia Jain, Eric Daar, Michael Dubé, Edward Seefreid, Eric Ellorin, Gustavo A. Jimenez-Maggiora, Sheldon R. Morris, Richard H. Haubrich, CCTG 592 Team

1University of Southern California Keck School of Medicine, Los Angeles, CA, United States; 2UC, San Diego, San Diego, CA, United States; 3Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, United States

**Background:** Improved programs to prevent and screen for sexually transmitted infections (STIs) and related risk behavior are needed among HIV-infected men who have sex with men (MSM). We piloted an internet-based safer sex intervention to reduce STIs, a biologic marker for high risk sexual activity, among HIV-infected MSM.

**Methodology:** Eligible subjects were HIV-infected MSM who reported recent unprotected sex or STIs. Participants at three Southern California HIV clinics were randomized (1:1) to either a monthly behavioral risk survey instrument alone or with tailored internet-based prevention messages based on their risk of HIV transmission (derived from self-reported risk behavior). The messages for the intervention arm targeted condom use, antiretroviral (ARV) use, disclosure of HIV status, and reducing substance use. STIs were assessed at baseline and then every three months, including for syphilis, gonorrhea and Chlamydia (latter two at urethra, anal and pharyngeal sites). The primary endpoint was any new STI event per subject over 12 month study period. Primary analysis was performed on a modified intention-to-treat (mITT) population (randomized subjects who completed a baseline visit) with a logistic regression model for the dichotomous outcome of any incident STI event that included treatment assignment, baseline STI status, ARV use, and methamphetamine use as predictors. A sensitivity analysis included those who completed ≥75% of their monthly visits.

**Results:** There were 181 MSM randomized, mean (SD) age 43.6 (11); 32.8% White, 31.7% Hispanic and 30.6% Black with 83.9% on ART with 35% having detectable viral load. Two did not complete their baseline visit resulting in a mITT sample of 179. There was no difference in attrition between the intervention (19%) and control (25%) groups (p=0.37). At baseline, 25 (28%) and 27 (30%) in the intervention and control arms, respectively, had a STI. Over the 12-month study period, 27 (30%) and 22 (27%) in the intervention and control arms, respectively, had at least one new STI. The multivariable logistic regression analysis on the mITT population showed no significant difference in the new STI event rates between the two arms (OR=0.74, 95% CI: 0.37-1.46, p=0.68). Limiting this analysis to those who completed ≥75% of monthly surveys (n=107) provided a similar result (OR=0.82, 95% CI: 0.32-2.11; p=0.68).

**Conclusions:** STIs were common in the HIV-infected MSM enrolled in this study. The internet-based risk reduction intervention showed no evidence for efficacy in reducing incident STIs among these subjects. Based on the primary endpoint, this study suggests that internet/computer-based safer sex programs such as the one utilized, are not effective for reducing high-risk sexual activity amongst HIV-infected MSM.
944 Changes in the Contribution (PAR%) of STIs To HIV Acquisition Among Kenyan FSWs From 1993 To 2012
Linnet Masese1, Jared M. Baeten2, Barbara A. Richardson2, Susan M. Graham1, Elizabeth Bukusi2, Juma Shafi3, James Kiarie4, R. Scott McClelland5
1University of Washington, Seattle, WA, United States, 2KEMRI, Nairobi, Kenya, 3University of Nairobi, Nairobi, Kenya, 4University of Nairobi, Nairobi, Kenya

Background: Genital infections including sexually transmitted infections (STIs) have been associated with an increased risk of HIV acquisition. Understanding how the contribution of different genital infections to HIV incidence has changed over the past two decades may be important for optimizing HIV prevention efforts. We assessed the population attributable risk percent (PAR%) of different genital tract infections, including STIs, to HIV acquisition in high-risk Kenyan women, from 1993 to 2012.

Methodology: We analyzed data from HIV-1-seronegative women in the Mombasa Cohort, a prospective cohort study of women reporting trading sex for cash or in-kind payment. Monthly HIV testing was performed using ELISA. We also performed monthly evaluation for genital tract infections including vaginal yeast, bacterial vaginosis (BV), Trichomonas vaginalis, Neisseria gonorrhoeae, non-specific cervicitis, and herpes simplex virus type 2 (HSV-2). We used Cox regression models to evaluate the association between different genital tract infections and HIV acquisition over 4 time periods (1993-1997, 1998-2002, 2003-2008 and 2008-2012). Each adjusted model addressed potential confounding factors including age, hormonal contraception, place of work, sexual risk behavior, and other genital tract infections. The resulting hazard ratios were used to calculate PAR%.

Results: Between 1993 and 2012, 2008 women contributed 6476 person-years of follow-up. The median age of participants at baseline was 28 years (interquartile range [IQR] 24-32). Most women worked in bars (N=1332, 66%), while the remainder worked in nightclubs (N=520, 26%) or at other venues (N=156, 8%). There were 325 incident HIV infections (incidence rate 5/100 person-years). In the overall adjusted analyses, vaginal yeast (HR 2.0; 95% confidence interval [CI] 1.6-2.6), BV (HR 1.5 95% CI [1.2-1.8], p=0.002), T. vaginalis (HR 1.5 95% CI [1.0-2.1], p=0.03), N. gonorrhoeae (HR 2.1 95% CI [1.4-3.1], p=0.001), and HSV-2 (HR 2.6 95% CI [1.5-4.3], p<0.001) were significantly associated with increased likelihood of acquiring HIV. The overall PAR% for each infection was: vaginal yeast (6.3%), BV (10.4%), T. vaginalis (1.2%), N. gonorrhoeae (1.0%), and HSV-2 (54.6%). The PAR% for trichomoniasis and gonorrhea remained <3% and the PAR% for vaginal yeast remained <8% across the four time periods. The PAR% for BV (8.6%, 19.0%, 13.7%, 12.6%), and HSV-2 (46.0%, 70.8%, 51.2%, testing in progress for 2008-2012) were higher, but varied somewhat over time.

Conclusions: Bacterial vaginosis and HSV-2 have remained the largest contributors to PAR% for HIV acquisition over the past 20 years. Interventions that prevent these conditions could provide the greatest potential benefit in terms of reducing HIV risk in women.

945 Intervention To Reduce HIV/STI Among High-Risk Patients in China: Cluster Randomized Trial
Don Operario1, Debin Wang2, Mei-Fen Yang1, Kathleen Blaney1, Jing Cheng2, Hong Qian2, Hongbo Zhang2, Gregory Szekeres2, Jerome Galea3, Thomas Coates3
1School of Public Health, Brown University, Providence, RI, United States, 2Anhui Medical University, Hefei, China, 3University of California Los Angeles, Los Angeles, CA, United States

Background: China is experiencing growing HIV and STI epidemics. Interventions to train physicians in China on HIV and STI knowledge, diagnosis, treatment, and risk reduction counseling can reduce HIV/STI risk transmission among high-risk patients.

Methodology: Cluster randomized trial. We randomized 51 counties in two provinces in eastern China to intervention or delayed-control groups. Physicians (n=120) in the intervention group counties received structured HIV and STI training and opportunities to enhance their clinical and counseling skills; physicians (n=128) in delayed group counties received the training after 9 months. We recruited 1,124 STI patients (4-6 from each participating physician), treated baseline gonorrhea and Chlamydia infections, and measured 9-month incident gonorrhea and Chlamydia infections, condom use, HIV/STI-related knowledge and attitudes, and satisfaction with their physician. Statistical comparisons between patients in intervention and control counties used multi-level analyses to account for cluster effects.

Results: At 9-month follow-up, patients in intervention counties had significantly lower odds of combined gonorrhea or Chlamydia reinfection (AOR = 0.62, 95% CI 0.46 - 0.84), lower unprotected sex (AOR = 0.22, 95% CI 0.12 - 0.42), greater HIV knowledge (adj. beta = 2.13, 95% CI 1.53 - 2.73), more positive attitudes toward people living with HIV (adj. beta = 1.51, 95% CI 0.96 - 2.05), and more positive ratings of physicians (adj. beta = 0.22, 95% CI 0.15 - 0.30), compared with delayed-control county patients.

Conclusions: Integrating HIV and STI training into medical education in China can be a useful strategy in reducing the country’s growing HIV and STI epidemics.

946 Validation of the Refined Denver HIV Risk Score Using a National HIV Testing Cohort
Jason Haukoos1, Emily Hopkins1, Meggan Buoss2, Michael Lyons1, Richard Rothman1, Douglas White1, Aila Al-Tayyib2, Lucy Brady-Springer1, Allison Sabel1, Mark Thrun1
1Emergency Medicine, Denver Health Medical Center, Denver, CO, United States, 2Emergency Medicine, University of Cincinnati, Cincinnati, OH, United States

Background: The Centers for Disease Control and Prevention (CDC) and US Preventive Services Task Force recommend routine HIV screening for adolescents and adults. Recently, the Denver HIV Risk Score (DHRS) was developed as a clinical prediction instrument to guide HIV screening by providing estimates of HIV infection risk. The DHRS has been refined to include only patient demographics, sex with a male, injection drug use, and past HIV test, but has not been broadly validated across different geographic regions or HIV testing venues. Our purpose was to externally validate the refined DHRS in a national HIV testing cohort from the CDC.
Methodology: This was a secondary analysis of HIV testing data from the Program Evaluation and Monitoring System of the CDC's National HIV Prevention Program. Data from all CDC-funded HIV testing sites in the U.S. with the exception of Massachusetts, North Dakota, Ohio and Rhode Island were included. Individuals ≥13 years of age who underwent HIV testing from January 1, 2008 through December 31, 2010 were used with newly-diagnosed HIV infection as the outcome. All observations were assigned scores according to the refined DHRS and categorized into 5 mutually exclusive groups: < 20 (very low risk); 20-29 (low risk); 30-39 (moderate risk); 40-49 (high risk); and ≥50 (very high risk). Proportions and 95% CIs for each group are reported. Calibration is reported as predicted versus observed HIV prevalence and discrimination is reported using a ROC curve and the areas under the curve.

Results: 4,830,941 testing events occurred, resulting in 30,080 (0.6%) newly-identified HIV infections. Of all visits, 432,674 (9%) were categorized as very low risk with an HIV prevalence of 0.20% (95% CI: 0.19%-0.21%), 1,312,427 (27%) were low risk with a prevalence of 0.17% (95% CI: 0.16%-0.17%), 2,003,857 (41%) were moderate risk with a prevalence of 0.39% (95% CI: 0.38%-0.40%), 811,501 (17%) were high risk with a prevalence of 1.19% (95% CI: 1.16%-1.21%), and 270,482 (6%) were very high risk with a prevalence of 3.57% (95% CI: 3.50%-3.64%). The DHRS demonstrated excellent calibration (regression slope = 1.09; R² = 0.99), good discrimination (ROC area = 0.77, 95% CI: 0.77 - 0.77), and similar accuracy across geographic regions.

Conclusions: The refined DHRS accurately categorized patients into significantly different HIV risk groups, regardless of geographic region. The refined DHRS is a relatively simple tool for quantifying HIV risk and may help identify individuals for HIV testing.

947 Cost Effectiveness of Antiretrovirals in HIV Control in Rural Zambia: A Stochastic League Approach

Brooke E. Nichols1, Rob Baltussen1, Janneke H. van Dijk1, Phil E. Thuma2, Jan L. Nouwen4, Charles A. Boucher1, David A. M. C. van de Vijver1
1Viroscience, Erasmus Medical Center, Rotterdam, Netherlands, 2Primary and Community Care, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands, 3Primary and Community Care, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands, 4Medical Microbiology and Infectious Diseases, Erasmus Medical Center, Rotterdam, Netherlands

Background: Earlier ART initiation and pre-exposure prophylaxis (PrEP) have both been demonstrated to effectively prevent new HIV infections. There is, however, limited funding available for HIV prevention. Choices must therefore be made when deciding on the optimal prevention strategy. The aim of this study was to compare the epidemiological impact, cost effectiveness and economic affordability of antiretroviral based prevention strategies.

Methodology: A deterministic mathematical model was made to predict the impact on the HIV-epidemic over 40 years of increasing the treatment initiation threshold to CD4 <500 cells/μl, and two hypothetical PrEP scenarios: prioritized to the most sexually active, and non-prioritized in the rural area of Macha, Zambia. We conducted a standard cost-effectiveness analysis by calculating incremental cost effectiveness ratios (ICERs) (an ICER of <$3480 is defined as cost effective in Zambia). It is important, however, to determine what cost effective intervention is affordable given a budget. We therefore implemented an economic analysis, stochastic league tables, which enable the prediction of the optimal intervention per budget level to explore both cost effectiveness and affordability.
Results: Continuing treatment at CD4 <350 will strongly reduce the HIV prevalence over time: from 6.2% (interquartile range 5.8%-6.6%) in 2014 to 1.3% (0.9%-1.9%) in 2054. All other interventions will result in prevalence of around 1% after 40 years, but result in infections averted (between 16% [prioritized PrEP plus treatment at CD4<350] and 59% [non-prioritized PrEP plus treatment at CD4<500]). The only strategy that was cost effective using standard cost effectiveness analysis was treatment at CD4 <500, with an ICER of $62 ($46-$75). Non-prioritized PrEP plus treatment at CD4 <500 was, however, borderline cost effective with an ICER of $5,861 ($3,959-$8,483). Based on current HIV treatment costs, it will cost on average $20 million to treat HIV at CD4 <350 over the coming 40 years in Macha. Initiating treatment at CD4 <500 would require a slight increase in budget up to $25 million, with a 96.7% probability of being the optimal intervention. Introduction of PrEP, however, is not included as an optimal intervention until the budget exceeds $180 million.

Conclusions: All prevention strategies avert new infections with a small impact on prevalence compared to baseline of treating at CD4<350. Following the WHO recommendation to start at a CD4 <500 would require only modest budget increases. While non-prioritized PrEP plus treatment at CD4 <500 is borderline cost effective, our stochastic league analysis shows that it is not economically feasible and should only be considered if there is a ten-fold increase in budget.

948 Darunavir(DRV)/r-Based PEP Versus Standard of Care (SOC) - the Randomized PEPDar Study
Gerd Fäktenheuer1, Norma Jung2, Heiko Jessen2, Albrecht Stobeh3, Keikawas Arasteh4, Johannes Bogner5, Christoph Stephan1, Christoph D. Spinner6, Olaf Dege6, Britta Ratneck7
1Med. Einrichtungen der Universität Köln, Cologne, Germany, 2Klinik I für Innere Medizin, Med. Einrichtungen der Universität Köln, Cologne, Germany, 3Praxis Jessen, Berlin, Germany, 4Zentrum Infektiologie, Ifi-institut für interdisziplinäre Medizin, Hamburg, Germany, 5Innere Medizin, Infektiologie und Gastroenterologie, Vivantes Auguste-Viktoria-Klinikum, Berlin, Germany, 6Medizinische Poliklinik, Ludwig-Maximilians-Universität, Munich, Germany, 7Zentrum der Inneren Medizin, Klinikum der Johann Wolfgang Goethe-Universität, Frankfurt, Germany, 8Zentrum für Medizinische Klinik und Poliklinik, Klinikum rechts der Isar, München, Germany, 9Bereich Infektiologie, Universitätsklinikum Eppendorf, Hamburg, Germany, 10Clinical Research, Janssen-Cilag, Neuss, Germany

Background: Post exposure prophylaxis (PEP) for 4 weeks is state-of-the-art following exposure to HIV with high risk of transmission. None of the recommended regimens has been studied in prospective randomised studies in this indication so far, discontinuations rates due to side effects are high. Darunavir/r has a favorable safety profile and high antiviral activity. It could therefore be an alternative to currently used drugs (mainly lopinavir (LPV)/r). This study was designed to generate data on safety and tolerability of DRV/r-based PEP compared to SOC-PEP.

Methodology: PEPDar was an open-label, randomized multicenter prospective noninferiority study enrolling patients following high risk exposure to HIV in Germany. Recommended SOC as per 2008 National Guidelines included 2 NRTIs plus LPV/r or EFV. Patients were stratified by risk of exposure (occupational [OE] vs. non-occupational [NOE]) to receive DRV/r + 2 NRTIs or SOC-PEP within 72 hours following high risk contact for 28-30 days. Primary endpoint was the early discontinuation rate (% subjects who discontinued HIV-PEP for >2 consecutive days prior to day 28) for any reason except documented negative HIV-status of the index person. The trial had 80% power to show noninferiority (overall significance level 5% [two-sided], non-inferiority margin 12%).

Results: Between 11/2011 and 05/2013 306 patients were enrolled at 22 centers. 82.7% were male (median age 33 years [range: 18-62]); 17.3 % were female (median age 31 years [range 18-55]). Median time between risk contact and start of PEP was 2 hours (range 0 - 22) after OE (n=62 [20.3%]) and 14 hours (range 0 -71.9) after NOE (n=244 [79.7%]). 155 patients received DRV/r + 2 NRTIs, 151 patients received SOC (LPV/r-based in all patients) + 2 NRTIs. 97% (n=298) received TDF/FTC as backbone. Early discontinuation rate was 5.8% (n=9) in the DRV/r-arm and 9.4% (n=14) in the SOC-arm showing non-inferiority (CI: -0.148; 0.078). Adverse events (AEs) related to DRV/r or SOC were recorded in 106 DRV/r-patients (68.4%) and in 114 SOC-patients (75.5%) (p=0.203). Most common AEs (all grades) were diarrhoea (28 vs. 42 patients [p=0.056]), nausea (16 vs. 26 patients [p=0.097]) and fatigue (17 vs.22 [p=0.393]). SOC-patients experienced more sleep disorders (0 vs. 6 [p=0.014]). Rash was reported in 6 DRV/r- patients and 5 SOC-patients. No seroconversion was documented.

Conclusions: DRV/r showed noninferiority with regard to early discontinuation of PEP when compared to SOC (LPV/r in all SOC-patients). Both regimens were well tolerated. We conclude that DRV/r-based PEP is an alternative to SOC including LPV/r.

949 High Initiation of PrEP and ART in a Demonstration Project Among African HIV-Discordant Couples
Renee Heffron1, Connie COLUM1, Nelly Mug012, Elly Kabatira3, Eliola Tumwegeti4, Jessica Haberer5, Jared Baeten1, for the Partners Demonstration Project Team
1University of Washington, Seattle, WA, United States, 2Kenya Medical Research Institute, Nairobi, Kenya, 3Makerere University, Kampala, Uganda, 4Integrated Community Based Initiatives (ICDBI), Busheyeni, Uganda, 5Massachusetts General Hospital, Boston, MA, United States, 6Harvard University, Boston, MA, United States

Background: PreP and ART have demonstrated high efficacy for HIV prevention among African HIV serodiscordant couples. Assessing delivery, uptake of and adherence to antiretroviral strategies for HIV prevention outside of clinical trial settings is a priority.

Methodology: Enrollment into an open-label demonstration project of PrEP and ART among high-risk, research-naive HIV serodiscordant couples from 4 sites in Kenya and Uganda began in November 2012. Couples are eligible if the HIV-infected partner is not on ART at enrollment. PrEP is offered as a bridge to ART initiation in the couple, in which ART is offered according to current national guidelines of Kenya and Uganda (CD4 ≤350 or symptomatic HIV disease). Tenofovir/emtricitabine PrEP is offered to couples in which the HIV-infected partner declines, delays, or is not eligible for ART, and during the first 6 months after the HIV-infected partner initiates ART, to allow time for achieving viral suppression. Couples are followed quarterly with counseling about HIV risk reduction strategies, ART benefits, ART and PrEP adherence counseling, and semiannual CD4 testing. ART adherence is assessed through biannual HIV RNA concentration measurements and PrEP adherence is assessed through medication event monitoring caps, pill counts, and tenofovir drug level testing.
**Results:** As of September 2013, 339 couples (70.2% in which the HIV-infected partner was female) were enrolled; with 96.6% of eligible couples enrolled. The median age is 29 years for HIV uninfected partners and 27 years for HIV infected partners. Most (94.4%) couples are married, 22.7% have no children, and the median number of children is 1. HIV-uninfected partners reported a median of 7 (IQR 3-12) sex acts with their study partner in the month prior to enrollment and 67.0% reported having unprotected sex. HIV-infected partners have a median CD4 count of 404 (IQR 256-595), median plasma viral load of 4.6 (IQR 4.0-5.0) log10 copies/mL, and 51.9% are eligible for ART. At enrollment, 97.3% of HIV uninfected partners initiated PrEP and 72.3% of ART eligible HIV infected partners initiated ART through on-site ART providers or accepted a referral to start ART at an off-site provider. Following the enrollment visit, only 2% of couples were not using PrEP or ART for prevention.

**Conclusions:** HIV serodiscordant couples from East Africa have high uptake of antiretroviral-based prevention and high rates of initiation of open-label PrEP and ART. Data from the ongoing study will be essential to guiding implementation and integration of antiretroviral-based prevention into policy.

---

**950 PrEP Is Efficacious for HIV Prevention Among Women Using DMPA for Contraception**

Renee Heftron1, Nelly Mugo1,2, Edwin Were1, James Kiarie4,5, Elizabeth Bukusi2, Andrew Mugisha2, Deborah Donnell1,6, Allan Ronald1, Connie Celum1, Jared Baeten1, for the Partners PrEP Study Team

1University of Washington, Seattle, WA, United States, 2Kenya Medical Research Institute, Nairobi, Kenya, 3Moi University, Eldoret, Kenya, 4Kenya National Hospital, Nairobi, Kenya, 5University of Nairobi, Nairobi, Kenya, 6Fred Hutchinson Cancer Research Center, Seattle, WA, United States, 7University of Manitoba, Winnipeg, MB, Canada

**Background:** Pre-exposure prophylaxis (PrEP), using daily oral tenofovir disoproxil fumarate (TDF) or combination emtricitabine (FTC)/TDF, is a proven HIV prevention strategy. Observational studies have suggested that the injectable contraceptive depot medroxyprogesterone acetate (DMPA) may increase the risk for HIV acquisition among women. Whether PrEP is efficacious for HIV prevention among women using DMPA has not been evaluated previously.

**Methodology:** In a randomized, placebo-controlled trial of PrEP among Kenyan and Ugandan HIV serodiscordant couples (the Partners PrEP Study), we estimated the efficacy of PrEP (TDF or FTC/TDF) for HIV prevention among HIV uninfected women using DMPA. HIV uninfected members of the couples were seen monthly and study visits included active HIV testing, study medication provision, and adherence counseling. Contraception was not required but were counseled to delay pregnancy until after this PrEP safety and efficacy study, and a variety of contraceptives were offered on-site, free-of-charge.

**Results:** 1785 HIV uninfected women participated in the trial, of whom 901 (50.5%) used DMPA at some point during follow-up, including 486 who were using DMPA at enrollment and 415 who initiated DMPA during follow-up. During follow-up, 45 women acquired HIV, of whom 15 (33.3%) were using DMPA at the time of HIV acquisition. Among women using DMPA, HIV incidence was 1.24 per 100 person-years for women assigned to active TDF or FTC/TDF PrEP and 3.75 per 100 person-years among women assigned placebo, translating into a 72% reduction in the risk of HIV acquisition from PrEP among women using DMPA (hazard ratio 0.28, 95% confidence interval 0.10 - 0.83, p=0.02). Sensitivity analyses with varied definitions of DMPA use, including DMPA use as reported at enrollment and a prolonged effect of DMPA for 70 days after last reported use, had similar findings.

**Conclusions:** PrEP is efficacious for HIV prevention among women using DMPA, suggesting PrEP could mitigate the potential increased HIV acquisition risk that has been associated with DMPA use in some observational studies. Strategies to integrate PrEP use and family planning counseling should be prioritized for women at high risk of HIV infection.

---

**951 PrEP Interest, Uptake, and Adherence Among Young Men Who Have Sex With Men (YMSM) in the United States**

Sybil Hosek1, Jaime Martinez2, Kristine Santos3, Megha Mehratra1, Christopher Balthazar1, Pedro Serrano1, Kelly Bojan1, Robert Grant1, The Adolescent Medicine Trials Network for HIV/AIDS Interventions

1Psychiatry, Stroger Hospital of Cook County, Chicago, IL, United States, 2Stroger Hospital of Cook County, Chicago, IL, United States, 3Ruth M. Rothstein CORE Center, Chicago, IL, United States, 4Gladsome Institutes, San Francisco, CA, United States

**Background:** Young men who have sex with men, particularly racial minority YMSM, are the only group in the United States whose HIV infection rates continue to increase. Pre-exposure prophylaxis (PrEP), which has been shown to reduce the risk of HIV acquisition, may be an ideal prevention method for these young men. Data on interest in open label PrEP use among MSM from the iPrex trial have been presented, yet YMSM in the United States were not included in those analyses. Understanding the interest, uptake, and adherence to PrEP among U.S. YMSM is critical for designing PrEP implementation programs domestically.

**Methodology:** All 68 YMSM previously enrolled in ATN 082, a randomized pilot trial of PrEP feasibility and acceptability, were eligible to enroll in the open label extension of the iPrex trial (iPrex OLE). All HIV-uninfected participants were offered daily PrEP (TDF/FTC) along with a comprehensive package of HIV/STI testing and integrated risk reduction/adherence counseling. All participants taking PrEP were tested for tenofovir levels via plasma. Participants completed detailed computer assisted self-interviews on reasons for study participation, knowledge of PrEP efficacy, PrEP adherence and sexual behavior. We compared rates of self-reported adherence, tenofovir drug levels, and sexual risk behavior between the ATN 082 and iPrex OLE.

**Results:** Forty-six YMSM (68% of total eligible; mean age 21; 52% Black, 37% Latino) enrolled in iPrex OLE. Of those, 69.6% chose to take PrEP. The most common reasons for study participation were to help fight the HIV epidemic (74%), to get tested for HIV (59%) and to protect against HIV (59%). Tenofovir detection during the first 12 weeks of iPrex OLE was 58.3% - up from 45% during the same timeframe of ATN 082. Self-reported adherence (64.8%) was consistent with tenofovir detection. Most common reasons for missing doses were not having pills with them (28%), schedule changes (24%) and forgetting (22%). Perceptions of PrEP efficacy increased significantly (p<.001) across study visits, while number of recent sex partners and episodes of unprotected anal receptive sex decreased. Participants reported multiple social benefits from study participation and 70% stated they would take PrEP in the future if available.
Conclusions: When offered open label access to an efficacious product, the majority ATN 082 participants chose to enroll in iPrEx OLE and take PrEP. While adherence among this challenging population was not optimal, it improved from ATN 082 and was consistent with self-report. YMSM may find both medical and social benefits to participation in PrEP programs as well as develop skills to improve adherence and decrease sexual risk behavior. YMSM appear interested and willing to take PrEP now that efficacy has been established.

**952 Early Adopters: Correlates of Chemoprophylaxis Use in an Online Sample of US Men Who Have Sex With Men**

**Kenneth H. Mayer**1, 2, Catie Oldenberg3, David Novak4, Douglas Krakower1, 2, Matthew Mimiga1, 3

1The Fenway Institute, Fenway Health/Harvard Medical School, Boston, MA, United States, 2Epidemiology, Harvard School of Public Health, Boston, MA, United States, 3Online Buddies, Cambridge, MA, United States

**Background:** Although HIV pre-exposure prophylaxis (PrEP) use has been shown to decrease HIV incidence among men who have sex with men (MSM), uptake has not been widespread, and the demographics and behaviors of those who initiated PrEP outside of studies is not well known.

**Methodology:** In August 2013, members of the largest MSM sexual-partner seeking networking site in the US received an online invitation to complete a survey about their HIV prevention practices. Responses were analyzed using summary statistics. Multivariable logistic regression analyses were conducted to determine adjusted odds ratios to assess factors associated with having used PEP or PrEP.

**Results:** Of 9,179 MSM who responded to the survey, 18% used mobile technology. Participants’ mean age was 26 years; 82% identified as homosexual or gay, 23.6% as bisexual, 2.4% as heterosexual, 0.4% as transgender and 1.1% as gender queer. Most of the respondents were white (85.7%), 3.9% Black, 7.5% Latino. Over 2/3 (68.4%) completed college. The sample was geographically diverse. More than ¼ (30.2%) reported a prior sexually transmitted infection (STI); 58.7% reported at least one episode of unprotected anal sex, and 7.5% reported substance use during sex in the prior 3 months. Although 84.0% reported that they had a primary care provider (PCP), only 53.9% reported that they felt comfortable discussing sex with their PCP. Only 3.2% of respondents reported prior PEP use, and 1.2% reported PrEP use. PEP users more often were younger, identified as gender queer (compared to homosexual or gay), had graduated college, had a prior STI diagnosis, engaged in recent unprotected anal sex, had used substances during sex, and were more comfortable talking about sex with their PCP compared to MSM who had not used PEP. PrEP users more often reported that they had graduated college, had a prior STI, and were more comfortable talking with their PCP about MSM sex compared to MSM who had not used PrEP. PrEP users had a 16-fold greater odds of having used PEP than PrEP-naive MSM.

**Conclusions:** Although MSM in this online survey reported significant HIV risks, their experience with PEP and PrEP was limited. In order to increase PrEP uptake among MSM, PCPs need to be educated to provide culturally competent care, so that patients can be comfortable discussing HIV risks that could be decreased by PEP or PrEP.

**953 Measuring Intermittent and Daily PrEP Adherence by Hair Levels, Self-Report and MEMS Caps Openings**

**Sanjiv M. Baxi**1, Albert Lu2, Peter Bacchetti3, Gaudensia Mutua4, Eduard Joachim Sanders5, Freddie M. Kibengo6, Jessica E. Haberer7, James Rooney8, Frances Priddy9, Monica Gandhi1

1Infectious Diseases, University of California San Francisco, San Francisco, CA, United States, 2San Francisco Department of Public Health, San Francisco, CA, United States, 3Epidemiology & Biostatistics, University of California San Francisco, San Francisco, CA, United States, 4Kenya AIDS Vaccine Initiative, Nairobi, Kenya, 5Centre for Geographic Medicine Research Coast, Kilifi, Kenya, 6Medical Research Council (MRC)/Uganda Virus Research Institute (UVRI), Entebbe, Uganda, 7Infectious Diseases, Center for Global Health, Boston, MA, United States, 8Gilead Sciences, Foster City, CA, United States, 9International AIDS Vaccine Initiative, New York, NY, United States

**Background:** Intermittent PrEP may facilitate adherence, reduce cost, and shows efficacy in simian models, but accurate measurement of adherence is critical for trial interpretation. Hair tenofovir (TFV) levels are strongly and linearly related to dose and predict HIV treatment responses, so may serve as objective markers of adherence. We compared TFV and emtricitabine (FTC) hair levels with traditional measures of adherence in two intermittent PrEP trials conducted in HIV serodiscordant couples in Uganda and men-who-have-sex-with-men (MSM) in Kenya.

**Methodology:** Each trial randomized HIV-negative individuals to daily versus intermittent (Mondays, Fridays, within 2 hours after sex other days) PrEP with FTC/TDF or placebo in a 2:2:1:1 ratio. Number of doses taken was assessed by self-report and medication event monitoring systems (MEMS); hair samples were collected and analyzed for TFV/FTC concentrations at weeks 8 and 16. Linear regression models with random intercepts analyzed relationships between logarithmically-transformed hair levels, MEMS and self-report.

**Results:** 172 hair samples from 88 volunteers randomized to daily or intermittent PrEP (active arms) were analyzed. Hair collection was highly acceptable (100% at week 8, 96% at week 16). Hair levels for those on daily doses averaged >2x (2.6x for FTC; 2.1x for TFV) those on intermittent dosing. Hair levels were rarely undetectable (<2.5%) at week 8, but were undetectable more frequently (with a significant difference for FTC) by week 16 (9.5% with undetectable FTC, p = 0.008; 4.8% with undetectable TFV, p = 0.35). Hair levels and MEMS counts were strongly associated: for every 10% increase in MEMS caps openings, TFV and FTC hair concentrations increased by 8% and 10%, respectively. Self-reported doses taken and TFV/FTC hair levels were weakly associated. Adjusting for other predictors (age, weight, height, hair color, gender, drug use, liver/renal function, dosing) did not substantially change estimated effects of MEMS counts on hair levels. MSM (Kenya) were estimated to have ~40% lower average TFV/FTC hair concentrations than heterosexual participants (Uganda), an observation only partially mediated by younger age.

**Conclusions:** In two intermittent PrEP trials in East Africa, hair collection was highly acceptable and feasible. Concentrations of TFV/FTC in hair were strongly associated with MEMS openings, but more weakly associated with self-report, likely reflecting biases of the latter. Hair levels in active arms were generally detectable, but there were more undetectable levels and fewer MEMS caps openings later in the trial. Hair concentrations were lower in MSM than heterosexual participants. Concentrations of TFV/FTC in hair should be investigated further as a promising measure of adherence in PrEP.
954 Implementation of PrEP in STD Clinics: High Uptake and Drug Detection Among MSM in the Demonstration Project
Stephanie E. Cohen1, Eric Vittinghoff2, Peter Anderson3, Susanne Doblecki-Lewis4, Oliver Bacon5, Wairimu Chege6, Richard Elion7, Susan Buchbinder8, Michael Kolber9, Albert Liu1
1Disease Prevention and Control, San Francisco Department of Public Health, San Francisco, CA, United States, 2Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA, United States, 3University of Colorado at Denver, Denver, CO, United States, 4University of Miami, Miami, FL, United States, 5Prevention Sciences Program, National Institutes of Health, Bethesda, MD, United States, 6Whitman-Walker Health, Washington, DC, DC, United States, 7Bridge HIV, San Francisco Department of Public Health, San Francisco, CA, United States

Background: Pre-exposure prophylaxis (PrEP) has been shown to be safe and efficacious in clinical trials. Demand for PrEP and levels of adherence in real world settings are unknown. We evaluated PrEP uptake and early drug detection among men who have sex with men (MSM) in the first year of a US PrEP Demonstration (Demo) Project.

Methodology: From 9/2012 to 9/2013, HIV-uninfected MSM and transgender women receiving services or requesting PrEP at STD clinics in San Francisco (SF) and Miami were offered the opportunity to screen for The Demo Project. Enrolled participants were offered up to 48 weeks of open-label emtricitabine/tenofovir. Predictors of PrEP uptake were assessed using multivariable logistic regression. Tenofovir diphosphate (TFV-DP) levels in dried blood spots (DBS) were assessed in a random sample of participants at the 4 week visit.

Results: Of 831 clients approached for participation in the Demo Project, 340 declined, 105 were ineligible based on behavioral or medical criteria, and 386 enrolled, for an overall uptake of 53% among potentially eligible clients (49% in SF vs. 64% in Miami). Mean age of enrolled participants was 35 years; 9% were African American, 35% Latino, and 46% white; 42% were uninsured and 73% had previously heard of PrEP. Participants in Miami were younger, more likely to be Latino or African-American, less likely to be insured, and less likely to report drug use or unprotected receptive anal sex in the prior 3 months (all p<0.05). In adjusted analyses, participants from Miami (AOR 6.5, 95% CI 2.9-14.8), with prior PrEP awareness (AOR 2.3, 95% CI 1.5-3.5), and those reporting unprotected anal sex with >5 partners (AOR 1.5, 95% CI 1.0-2.2) or >1 episode of anal sex with an HIV-infected partner (AOR 1.8, 95% CI 1.2-2.6) in the last 12 months were more likely to enroll in the Demo Project. In SF, higher risk perception (AOR 1.9, 95% CI 1.2-2.8) was also associated with enrollment. DBS samples from 87 participants at week 4 were tested: almost all had TFV-DP detected (100% in SF, 95% in Miami). Median TFV-DP levels were higher in SF than in Miami (975 vs. 658 fmol/punch, p<0.001), and a greater proportion of participants from SF had TFV-DP levels consistent with having taken at least 4 doses/week (92% vs. 57%, p<0.001) (Fig 1).

Conclusions: Demand for PrEP and rates of early drug detection are high among MSM in the first year of the Demo Project. Factors contributing to differences in PrEP uptake and adherence across sites warrant further investigation.

955 High Medication Adherence Among HIV-1 Uninfected Women Experiencing Pregnancy in a PrEP Trial
Lynn T. Matthews1,2, Renee Heffron3, Nelly R. Mugo3,4, Craig R. Cohen5, Craig W. Hendrix6, Connie Celum3,7, David R. Bangsberg1, Jared M. Baeten3,7, for the Partners PrEP Study Team
1Division of Infectious Disease & Center for Global Health, Massachusetts General Hospital, Boston, MA, United States, 2Division of Infectious Disease, Beth Israel Deaconess Medical Center, Boston, MA, United States, 3Department of Global Health, University of Washington, Seattle, WA, United States, 4Department of Obstetrics and Gynecology, Kenyatta National Hospital, Nairobi, Kenya, 5Department of Obstetrics, Gynecology, and Reproductive Sciences, University of California San Francisco, San Francisco, CA, United States, 6Department of Medicine, Johns Hopkins University, Baltimore, MD, United States, 7Department of Medicine, Department of Epidemiology, University of Washington, Seattle, WA, United States

Background: Pre-exposure prophylaxis (PrEP) may be an important safer conception strategy for HIV-1 uninfected women with an HIV-1 infected partner. Identifying pregnancy predictors and medication adherence in this population may inform whether PrEP is a feasible safer conception strategy.

Methodology: We evaluated predictors of pregnancy and adherence to study medication among HIV-1 uninfected women enrolled in a randomized, placebo-controlled trial of oral, daily PrEP among African HIV-1 serodiscordant couples. Participants were counseled on HIV-1 risk reduction, contraception,
and PrEP adherence at monthly study visits. Monthly visits included pregnancy testing with urine β-hCG. Pill count adherence was calculated from monthly clinic counts of dispensed and returned study pills and stored plasma from selected study visits was tested for tenofovir drug concentrations.

Results: Among 1785 women whose median age was 33 years (IQR 28-38), pregnancy incidence was 10.2 per 100 person-years. Younger age, not using contraception, having an additional sexual partner, and reporting unprotected sex were associated with increased likelihood of pregnancy. PrEP adherence was high among women who became pregnant: monthly clinic pill counts of study medication demonstrated 98% of prescribed doses were taken and tenofovir was detected in 71% of plasma samples tested. Adherence was similarly high in the months prior to conception in comparison to prior periods (Figure 1).

Conclusions: HIV-1 uninfected women with known HIV-1 infected partners had 10% annual pregnancy incidence in a clinical trial with excellent access to effective contraception. Women who became pregnant had high medication adherence, suggesting that PrEP may be an acceptable and feasible safer conception strategy for HIV-1 uninfected women in an HIV-1 serodiscordant partnership.

956 Willingness To Use Pre-Exposure Prophylaxis Among Community-Recruited Injection Drug Users

Irene Kuo1, Gregory L. Phillips2, Manya Magnus1, Janevieve Opoku1, Anthony L. Rawls2, James Peterson1, Michael Kharfen1, Alan E. Greenberg2
1George Washington University School of Public Health and Health Services, Washington, DC, United States, 2Department of Epidemiology and Biostatistics, George Washington University School of Public Health and Health Services, Washington, DC, United States, 3HIV/AIDS, Hepatitis, STD and TB Administration, District of Columbia Department of Health, Washington, DC, United States

Background: Recent evidence indicates that using antiretrovirals as pre-exposure prophylaxis (PrEP) among injection drug users (IDUs) is effective in preventing HIV transmission. We examined the correlates of the willingness to use PrEP among community-recruited active IDUs in Washington, DC.

Methodology: Data from the IDU cycle (2012) of the National HIV Behavioral Surveillance system in DC were used. IDUs were recruited using respondent-driven sampling (RDS) and completed a detailed behavioral quantitative interview and underwent rapid testing for HIV. Data were limited to HIV-negative IDUs who reported on willingness to use PrEP and how it might affect their drug use and sexual behaviors. RDS-weighted proportions and correlates of self-reporting being very likely to use PrEP using unweighted multivariable analyses were reported. Potential correlates included demographic characteristics, sexual and drug use behaviors, institutional history, depressive symptoms, and utilization of needle exchange programs. Variables attaining a univariate p-value of ≤0.05 were included in the final model.

Results: Among 304 HIV-negative IDUs, 68.0% were male, and 82.7% were 50 or older, 97.2% were black, and 69.3% had a high school diploma or higher; the majority were unemployed or disabled. None had ever taken PrEP. 47.4% reported being very likely and 23.6% reported being somewhat likely to take PrEP if it were available and free, and 88.0% and 87.9% disagreed that they would no longer need to sterilize/clean needles or use condoms during sex if taking PrEP, respectively. Independent correlates of reporting being very likely to use PrEP included being younger (<50 years old; aOR: 2.68, 95% CI: 1.18, 6.11) and having two or more sex partners in the past 12 months compared to having none (aOR: 5.03; 95% CI: 1.82, 13.9).

Conclusions: A large proportion of active IDUs in Washington, DC reported being willing to use PrEP if it were available at no cost. IDUs who were younger and had more sex partners reported to be more willing to use PrEP, suggesting that these groups could be targeted first to explore the practicality of PrEP use in this population. Further research should be done to explore availability, uptake, and adherence of PrEP among IDUs.

957 PrEP Does Not Diminish the Pregnancy Prevention Effectiveness of Hormonal Contraception

Pamela M. Murnane1, Renee A. Heffron1, Connie Celum1, Elizabeth Bukusi1, Deborah Donnell2, James Kiarie1, Nelly Mug02, Allan Ronak1, Edwin Were1, Jared Baeten1
1University of Washington, Seattle, WA, United States, 2University of Nairobi, Nairobi, Kenya

Background: Pre-exposure prophylaxis (PrEP) is highly effective for HIV-1 prevention. Some studies have suggested an antagonistic interaction between PrEP and hormonal contraception, with both biologic and behavioral mechanisms hypothesized. Evidence is needed to ensure PrEP and hormonal contraception can be effectively used together. We evaluated whether PrEP reduces hormonal contraceptive effectiveness for pregnancy prevention.

Methodology: In a clinical trial of PrEP (the Partners PrEP Study), 1785 HIV-1 uninfected women and their HIV-1 infected male partners were randomized to tenofovir or co-formulated tenofovir-emtricitabine PrEP or placebo and followed for up to 3 years. Contraception was not required for study participation, was offered on-site, and was recorded monthly; incident pregnancy was determined by monthly urine pregnancy testing. We estimated the contraceptive effectiveness of hormonal contraceptive methods (oral contraceptive pills, injectable contraception, and contraceptive implants) compared to no
Participants were enrolled from October 2013 to June 2014. Within the first 6 months, a total of 413 participants were enrolled. Of the 413, 161 (38.9%) have completed visit 1 with 102 (63.3%) testing positive for HIV. Thirty eight (37.2%) HIV-infected participants were on ART at the time of recruitment while 64 (62.8%) were ART-naïve and referred for ART preparation. Of these 64, 17 (26.6%) did not complete the 1st session. Of the 47 who completed the 1st session, 23 (48.9%) and 3 (6.4%) did not complete the 2nd and 3rd session, respectively. Overall, of these 64, only 24 (37.5%) ART-naïve participants engaged in timely TasP. For participants who started ART, the median time from HTC to ART initiation was 26.5 days (range: 6 - 107 days). Compared to MSM who engaged in TasP, those who did not engage had significantly higher mean CD4 count (p=0.016), were more likely to be Muslims (p=0.024), younger (p=0.032), and of lower income status (p=0.028). Reasons given for lack of engagement in TasP included denial of HIV status, fear of medication side effects, perception of high CD4 count, and frequent travels.

Conclusions: Although, there was high acceptance of HTC among this MSM population, a high proportion did not engage in TasP, suggesting that customized treatment preparation for this high risk population may be necessary.

---

**959LB FEM-PrEP: Participant Explanations for Non-Adherence**

Amy Cornell1, Brian Perry1, Kawango Agot2, Khatija Ahmed3, Kevin McKenna1, Fulufhelo Malamatsho1, Jacob Odhiambo1, Joseph Skhosana1, Lut Van Damme1, FEM-PrEP study team

1Social and Behavioral Health Sciences, FHI 360, Durham, NC, United States; 2Impact Research and Development Organization, Kisumu, Kenya; 3Seshabwa Research Centre, Pretoria, South Africa; 4The Bill & Melinda Gates Foundation, Seattle, WA, United States

**Background:** FEM-PrEP - a clinical trial of daily emtricitabine/tenofovir disoproxil fumarate (FTC/TDF) for HIV prevention - was unable to determine the effectiveness of FTC/TDF among women in sub-Saharan Africa due to low study product adherence. We implemented a follow-up study to identify factors that influenced participants’ non-adherence and reasons for participation.

**Methods:** Using respondent driven sampling (RDS), MSM who were >16 years old and have engaged in either receptive or insertive anal intercourse within the previous 12 months were recruited into a prospective combination HIV prevention and treatment study (TRUST). Two weeks after enrollment, HIV testing and counseling (HTC) was conducted. During every 3 month follow-up visits, all HIV-uninfected participants underwent repeat HTC; HIV-infected participants underwent clinical and laboratory evaluation, including CD4 count, plasma HIV viral load, immediate 3 weekly sessions of ART preparation, then ART initiation per TasP strategy irrespective of CD4 count. Reasons for not engaging in ART preparation and/or non-initiation of ART were documented. Characteristics associated with TasP engagement were determined using Chi-square; a double sided p-value <0.05 was considered significant.

**Results:** Among women reporting no contraceptive use, pregnancy incidence was 14.6% per year among women assigned PrEP and 17.4% per year among women assigned placebo (Table). Women reporting oral contraceptive use had similar pregnancy incidence compared to women using no contraception and this effect was similar for women assigned PrEP and placebo (interaction p=0.22). Women reporting injectable contraception had substantial protection from pregnancy which did not differ by randomization arm (PrEP: HR 0.3, p<0.001; placebo: HR 0.2, p<0.001; interaction p=0.45). Contraceptive efficacy was highest among women using contraceptive implants (incidence <1%/year).

**Conclusions:** PrEP had no adverse impact on contraceptive effectiveness for pregnancy prevention. As seen in prior studies in similar populations, oral contraceptive pills provided little reduction in pregnancy incidence, possibly due to poor adherence. A combination of injectable or implantable hormonal contraception plus PrEP provides effective prevention for pregnancy and HIV-1.
Methodology: We conducted qualitative, semi-structured interviews (SSIs) (n=88) and quantitative audio computer-assisted self-interviews (ACASI) (n=224) with FEM-PrEP participants in Bondo, Kenya, and Pretoria, South Africa. SSI participants were purposefully sampled to represent a range of drug concentrations. The ACASI questionnaire was completed by most SSI participants (n=86), a randomly selected group of participants assigned placebo (n=50), and a separate group interviewed about risk perceptions (n=88). We used thematic analysis and descriptive statistics to analyze the qualitative and quantitative data, respectively. Ickovics’ and Meisler’s conceptual framework on adherence was used to better understand behavioral and contextual factors surrounding adherence.

Results: Table 1 lists factors influencing non-adherence, as reported in ACASI, for four of the five categories of the framework. Reasons for trial participation may be indirectly related to the fifth category - clinical setting (e.g., services): 93% of participants said they participated in FEM-PrEP because of indirect benefits (e.g., medical care). In the SSIs, participants frequently mentioned several individual and regimen-related factors as reasons other participants were non-adherent, including lack of support or discouragement from others, unknown effectiveness of FTC/TDF and unknown pill randomization, perceptions of low or variable HIV risk, large pill size, concerns about side effects, and the uncommon practice of taking pills when not sick.

Conclusions: Use of an investigational drug was a prominent concern among participants from both sites, although especially in Pretoria. Unacceptability of a daily pill as PrEP for some participants, particularly among women in Pretoria, and negative influences from others also influenced adherence within the context of a clinical trial. The trial’s indirect benefits may have encouraged women who were not interested in taking the study product to enroll. Alternative study designs/procedures and enhanced community engagement paradigms may be needed in future studies.

960 Prevention of HIV Transmission With Post-Exposure Prophylaxis After Infected-Blood Transfusion
Sami H. Al Hajjar1, Husn H. Frayha1, Mohammad Al Hazmi2, Reem Batteri2, Kenneth Mcintosh3, Paul E. Sax4, Emily Hanhauser5, Daniel R. Kulltaske5, Jonathan Z. Li5, Timothy J. Heinrich4
1King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, 2King Fahd Central Hospital, Jazan, Saudi Arabia, 3Boston Children’s Hospital, Harvard Medical School, Cambridge, MA, United States, 4Brigham and Women’s Hospital, Harvard Medical School, Boston, MA, United States, 5Brigham and Women’s Hospital, Harvard Medical School, Cambridge, MA, United States

Background: Without intervention, 90% of recipients transfused with HIV-infected blood are expected to become infected. While post-exposure prophylaxis (PEP) is commonly prescribed in the setting of non-occupational HIV exposures, there is very limited evidence documenting efficacy in this setting. We report the successful use of combination PEP following transfusion of HIV infected blood from a virologic donor source.

Methodology: A 12 year old girl with vaso-occlusive sickle cell crisis inadvertently received 1 unit of packed red blood cells from a donor subsequently found to be HIV-1 infected with plasma HIV RNA of 9740 copies/mL (not on antiretroviral therapy [ART]). Longitudinal testing of the patient’s plasma and peripheral blood mononuclear cells (PBMCs) was performed by commercial laboratory tests and by highly sensitive research assays with thresholds of detection down to 0.07 DNA copies/10^6 PBMCs and 0.4 RNA copies/mL of plasma during directly observed combination antiretroviral therapy (cART) and up to 3 months after cessation of cART. Serial HIV-1 antibody measurements were also obtained.

Results: Approximately one day after the transfusion, the patient had a positive HIV ELISA and confirmatory western blot (WB), but was negative for HIV DNA by PCR. The reactive bands on WB were identical in the donor and the recipient (GP120, GP41, GP31, P24 and P17). After prompt recognition of the infected transfusion and referral to a local medical center, she was started on tenofovir, emtricitabine, ritonavir-boosted darunavir (subsequently changed to lopinavir), and raltegravir 22 hours after the start of transfusion. She demonstrated no signs or symptoms of acute HIV infection and received 13 weeks of cART in a tertiary care center under direct observation. Longitudinal testing of HIV-1 DNA and RNA by both commercial and highly sensitive research assays was negative during and 3 months after stopping cART. HIV antibody became undetectable 7 months after the exposure.
**Conclusions:** We demonstrate that PEP initiated shortly after infusion of HIV-1 infected blood products can prevent HIV-1 transmission, even when exposure leads to positive HIV-1 serologies. The observation that no HIV-1 DNA or RNA has been detected in blood after stopping cART and that antibody became undetectable over time strongly suggests that PEP prevented establishment of a viral reservoir. This case also cautions that the presence of positive screening antibody reactivity immediately following exposure to HIV-infected blood products may be difficult to interpret and highlights the potential use of ultra-sensitive HIV-1 assays to guide management in this setting.

**961 Contingency Management Facilitates PEP Completion Among Stimulant-Using MSM**

**Raphael J. Landovitz1, Jesse B. Fletcher1, Steve Shoptaw2, Cathy J. Reback2**

1Center for Clinical AIDS Research & Education, University of California, Los Angeles, Los Angeles, CA, United States, 2Friends Community Center, Friends Research Institute, Los Angeles, CA, United States

**Background:** Post-exposure prophylaxis (PEP) is an emergency chemoprophylactic intervention after an exposure to viral inoculum. Stimulant-using (SU) MSM are at high risk of HIV acquisition, but are a challenging population in which to implement PEP. CM is a robust intervention that provides voucher-based incentives for stimulant-use abstinence, and has been shown to be a powerful and durable substance-use intervention. We previously reported that in a single-arm pilot intervention of PEP combined with CM in methamphetamine-using MSM, time to PEP initiation, adherence, and course completion rates were not different from historical non-SU populations.

**Methodology:** We conducted a prospective, randomized controlled trial of CM with PEP among SU MSM at a single site in Los Angeles, California. Participants enrolled in the study were randomized to CM or non-contingent (NC) control behavioral intervention and followed prospectively. Generalized linear models were used to estimate the effect of CM on likelihood of PEP course completion, rates of medication adherence, stimulant use and self-reported sexual risk behaviors. All analyses controlled for participant sexual identity, race/ethnicity, housing status, and income.

**Results:** Between June, 2010 and June, 2012, 140 MSM individuals were enrolled and randomized to CM (n=70) or a NC (n=70) behavioral intervention. The participants were 37% Caucasian, 37% African American, and 18% Latino. Mean age was 36.8 (SD 10.2) years, 61% had high school education or less, and 88.4% reported an annual income <$30,000. 45 participants (32%) initiated PEP after a high-risk sexual exposure during the study period, with a mean exposure-to-PEP time of 35.2 hours. 29 of the 45 had evaluable adherence data. PEP course completion was significantly greater in the CM arm compared to the NC arm (AOR 7.2, 95% CI 1.1-47.9), and there was a trend towards improved medication adherence by self-report in the CM arm (AOR 4.33, 95% CI 0.76-21.86). CM participants had a greater probability of stimulant-free urine specimens vs. NC participants (IRR 1.57, 95% CI 1.12-2.22), and a trend towards reduced episodes of UAI (IRR 0.34 [95% CI 0.11-1.08]). One HIV seroconversion was observed in the context of repeat exposures, and is unlikely to represent PEP failure.

**Conclusions:** In a randomized, controlled trial of SU MSM, CM facilitated the use of PEP by increasing rates of course completion, and suggesting a trend toward improved adherence. Reductions in sexual risk afforded by the CM intervention are a prime example of HIV prevention synergy. Despite small numbers of individuals initiating PEP, findings suggest that CM may be a useful support mechanism for the use of PEP, and potentially other biomedical prophylactic strategies in stimulant-using MSM.

**Circumcision**

**962 Male Circumcision: Association With HIV Prevalence, Knowledge, and Attitudes Among Women**

**Bertran Auvert1, Pascale Lissouba1, Dirk Taljaard2, Gilles Peytavin3, Beverley Singh2, Adrian Puren3**

1University of Versailles, Villejuif, France, 2INSERM, Villejuif, France, 3CHAPS, Johannesburg, South Africa, 4APHP, Paris, France, 5NHLS-NICD, Johannesburg, South Africa, 6NHLS-NICD, Johannesburg, South Africa

**Background:** Little is known on the impact of the current rollout of voluntary medicalized male circumcision (VMMC) in Africa among women. We studied the association of sexual partners’ male circumcision (MC) status with HIV prevalence among women, and their knowledge and attitudes regarding MC. This ANRS-12126 study took place in the township of Orange Farm (110 000 adults), South Africa, where a VMMC rollout program was set up in 2008. In three years, MC prevalence increased from 12% to 53%, and HIV prevalence among circumcised men was 48% lower than among other men.

**Methodology:** Three random independent cross-sectional surveys were conducted in 2008, 2010 and 2012 among 5 561 women aged 15 to 49. Blood samples were tested for HIV. Background information and sexual behavior, reported sexual partners’ MC status, and knowledge and attitudes regarding MC were collected. Prevalence rate ratios (PRR) and adjusted PRR (aPRR) were calculated using Poisson regressions.

**Results:** HIV prevalence was 30.1% (831/2 748), peaking at 47.8% (328/686) in the 30 to 34 age group. Among women ever having had sex, 30.0% (1 363/3 178) reported having had only circumcised partners. HIV prevalence among these women was lower than among other sexually active women 22.4% (305/1363; 95%CI: 20.3% to 24.9%) vs 36.6% (1 164/3 178; 95% CI: 35.0% to 38.2%), with PRR=0.72; 95%CI: 0.64 to 0.80; p<0.001, and aPRR=0.85; 95%CI: 0.76 to 0.95; p=0.004.

Among the reported 3 571 non-spousal sexual partnerships of the last 12 months, prevalence of consistent condom use was 37.5% (866/2 309) with circumcised partners and 38.6% (487/1 262) with uncircumcised partners (aPRR=1.00; 95%CI: 0.91 to 1.09; p=0.952).
Among the 2,200 women having had sex with circumcised and uncircumcised men, 74.4% (1,636) reported preferring circumcised partners, 3% (66) uncircumcised partners and 22.6% (498) had no preference.

Between 2008 and 2012, the proportion of women willing to have their male children circumcised increased from 83.0% (861/1,037) to 96.0% (2,311/2,407) \( p < 0.001 \).

In 2010 and 2012, among 3,496 women, 90.6% reported that circumcised men could become infected with HIV. About 1% believed that they were fully and 8.6% partially protected when having unprotected sex with a circumcised HIV positive partner. Moreover, 55.1% asserted that condom use was easier for circumcised men, 20.4% that it was not, and 24.5% did not know.

**Conclusions:** The findings on the association of women's HIV prevalence with their sexual partners' MC status are probably due to the lower HIV prevalence rate among circumcised men. Data reveals women's satisfactory knowledge and attitudes regarding MC. This study is encouraging for the current rollout of VMMC. Incidence studies are needed to investigate the association of VMMC rollout with HIV among women.

**963** Lower Odds of HIV Among Circumcised MSM in China and Interaction With Anal Sexual Role

Han-Zhu Qian\(^1\), Yuhua Ruan\(^1\), Yu Liu\(^1\), Douglas F. Milam\(^1\), Hans M. L. Spiegel\(^2\), Lu Yin\(^1\), Yiming Shao\(^2\), Sten H. Vermund\(^3\)

\(^1\)Vanderbilt University, Nashville, TN, United States, \(^2\)Chinese Center for Disease Control and Prevention, Beijing, China, \(^3\)JH-DAIDS, Bethesda, MD, United States

**Background:** Male circumcision reduces heterosexual acquisition of HIV, but evidence for its efficacy for preventing transmission among men who have sex with men (MSM) is unconvincing. We evaluated the association of male circumcision and odds of HIV and syphilis among Chinese MSM and the interaction between circumcision and anal sexual role on the relationship.

**Methodology:** During 2010–2011, we conducted a cross-sectional study among 1,155 MSM who were living in Beijing, China. Each participant completed a standardized questionnaire to collect demographic/sexual behavior information. Circumcision status was evaluated by both questionnaire self-reporting and by genital examination; and both HIV and syphilis infections were assessed with blood screening serology and confirmatory testing. We compared two methods for ascertaining circumcision; we performed both stratified analysis by anal sex role and multivariate logistic regression analysis for assessing the relationship of circumcision and HIV risk.

**Results:** Compared to uncircumcised men who practiced predominantly receptive or versatile anal sex, the adjusted risk of HIV among uncircumcised men practicing predominantly insertive anal sex was lower by 57% (adjusted odds ratio [aOR], 0.43; 95% confidence interval [CI], 0.32–0.59). Among circumcised men practicing predominantly receptive or versatile anal sex, it was lower by 52% (aOR, 0.48; 95% CI, 0.22–1.02), and among circumcised men practicing predominantly insertive anal sex was lower by 85% (aOR, 0.16; 95% CI, 0.04–0.65). After adjusting for demographic covariates and anal sex role, male circumcision was associated with a 54% lower odds of being HIV seropositive (aOR, 0.46; 95% CI, 0.24–0.89). Circumcision was not significantly associated with syphilis protection (aOR, 0.79; 95% CI, 0.45–1.42). The circumcision rate by self-report (10.4%) was higher than by genital exam (8.2%; \( \kappa = 0.809, P < 0.01 \)). Prevalence of HIV in those MSM without prior known HIV infection was 5.3% (48/913). Syphilis prevalence in all MSM was 26.1% (298/1,140).

**Conclusions:** Circumcised MSM were less likely to have acquired HIV, especially among men practicing predominantly insertive anal intercourse. Circumcision may be a more viable and efficacious global HIV prevention strategy for MSM that hitherto realized. Given methodological limitations in observational studies, a randomized clinical trial is needed to evaluate circumcision acceptability and efficacy among MSM in diverse settings.

**964** Client Experiences of Odor Associated With PrePex™ Device Male Circumcision in Botswana

Adrian Musiige\(^1\), Tigistu A. Ashengo\(^2\), Lesego Busang\(^1\), Kenanao Motlhola\(^1\), Alex Chipara\(^1\), Galina Stoliarzky\(^1\), Frank Mwanga\(^2\), Conrad Ntsuape\(^2\)

\(^1\)Jhpiego, Botswana; \(^2\)Jhpiego and Johns Hopkins University School of Public Health, Baltimore, MD, United States, \(^3\)African Comprehensive HIV/AIDS Partnerships (ACHAP), Botswana, Botswana; \(^4\)Ministry of Health of Botswana, Botswana, Botswana

**Background:** PrePex(TM) is a male circumcision device currently being studied for safety and acceptability. The foreskin tissue remains intact for the 7 days PrePex(TM) is worn, creating a microbiome that favours anaerobic bacterial growth that can be malodorous. Some clients complain of malodor while wearing PrePex(TM), which might influence the acceptability of the device. We present preliminary results on PrePex(TM) client experiences, perceptions, and practices related to malodor, about which no detailed report exists in present literature.

**Methodology:** We surveyed 734 of the 805 target sample of men aged 18–49 years who enrolled in an on-going PrePex(TM) safety and acceptability study in Botswana between May and September 2013. On the device removal visit, participants were asked about odor experiences, including noticeability, effect on activities of daily living (ADL), and remedies to combat odor. The Wilcoxon Two-Sample Test was performed to assess statistical significance of differences in the responses.

**Results:** 734 of men median age 26 years (SD = 7.08) responded to odor survey questions. 688 (94%) men reported to have noticed an unpleasant odor while the PrePex device was in situ. Of these, 37.1% noticed it by day 2 post-placement. A total of 45.7% of clients who noticed an odor were not disturbed by it, while 40.1% reported “some discomfort,” and 14.2% felt “very uncomfortable” from the odor. A total of 17.2% of clients reported that another person, mainly a partner or another family member, also noticed the odor. There was no association between family size and likelihood of another person to notice smell (\( \chi^2 = 105.4, \) \( df = 4 \)). About 1% mentioned using or discussing body perfumes. Of those, an equal proportion (23.3%) of clients felt remedies “helped a lot” as those who felt remedies “did not help”. Clients with large family size were more likely to try

965  Penile Cytokines Correlate With HIV Target Cells and Decrease After Circumcision in Rakai, Uganda

Jessica L. Progd1, Brett Shannon1, Kamoosh Shahabi1, Xiangrong Kong2, Cindy M. Liu3, Lance Price4, 5, Godfrey Kigozi2, David Serwadda2, Ronald H. Gray1, Rupert Kauf1, 2,式

Abstract

Background: Adult male circumcision (MC) reduces HIV acquisition by >50% in heterosexual men, but the mechanism of this protection is not completely understood. Recent evidence showed that MC reduces penile pro-inflammatory anaerobes; and since HIV preferentially infects activated CD4 T cells, this may represent one protective mechanism of MC. We hypothesized that MC reduces activated CD4 T cells in penile tissue; however, penile tissue cannot be biopsied post circumcision. We therefore first identified cytokines in penile swabs that correlate with the number of activated CD4 T cells in foreskin tissue. We measured these cytokines in swabs collected in a large, randomized trial of MC pre- and post-circumcision as a surrogate of changes in activated CD4 T cell density following circumcision.

Methodology: Foreskin tissue and coronal sulcus swabs were collected in a cross-sectional study of 89 men undergoing elective MC. Tissue density of HIV-target cells was determined with a combination of flow cytometry and immunochemistry; levels of 14 cytokines and chemokines were measured in swabs with an electrochemiluminescent multiplex ELISA. We then measured cytokine and chemokine levels in swabs collected from 111 men randomized to circumcision and 107 uncircumcised controls during a clinical trial of MC in Rakai, Uganda. Swabs were collected at enrolment and at 6, 12 and 24 months, and cytokine levels were compared between control and intervention men using generalized linear modeling.

Results: In the cross-sectional study, we found that levels of IL-8 in coronal sulcus swabs correlated with the tissue density of highly HIV-susceptible CD4 T cells, including Th17, Th1 and CCR5+ CD4 T cells (all p<0.05), but not Tregs. In the longitudinal study, pre-circumcision cytokine levels were similar between control and intervention men, but after 6 months MC was associated with a reduction in IL-8 relative to controls (adjusted PRR 0.67, 95% CI: 0.52, 0.87), and this differential increased over the 2 years of follow-up. No cytokine changes were observed in uncircumcised men, and MC was not associated with changes in vaginal cytokines among female sexual partners.

Conclusions: Levels of IL-8 on the foreskin surface correlates with the density of highly HIV-susceptible CD4 T cell populations in the underlying foreskin male circumcision is associated with reduced IL-8 on the coronal sulcus, suggesting reduced HIV acquisition after MC may be partly due to a reduction in penile inflammation, and thus HIV-susceptible cells, in remaining penile tissue.

966  HIV Shedding From Male Circumcision Wounds in Rakai, Uganda

1Johns Hopkins University, Baltimore, MD, United States, 2Rakai Health Sciences Program, Entebbe, Uganda, 3National Institutes of Health, Bethesda, MD, United States

Abstract

Background: A randomized controlled trial of circumcision of HIV-positive men reported increased HIV transmission to female partners among men who resumed sexual intercourse prior to wound healing. The effect of male circumcision (MC) on penile HIV wound shedding post-operatively is unknown. We conducted a prospective cohort study among men in Rakai, Uganda to assess HIV shedding post-MC.

Methodology: HIV shedding was evaluated among 189 HIV-infected men aged 12 years and above prior to MC, during surgery, and then for six weeks post-operatively in Rakai, Uganda. All men underwent dorsal slit MC. There were 60.5% (112/185) of men who had CD4 count ≥350 mm3 and 39.5% (73/185) who had a CD4 <350 cells/mm3. Weekly penile lavages of the MC surgical wounds were tested for HIV shedding and viral load using a real-time quantitative PCR assay (Abbott Molecular, Abbott Park, IL). Viral load was log10 transformed.

Results: HIV shedding was detected in 10.9% (20/184, 95%CI = 6.8%-16.3%) of men prior to MC and 60.1% (107/178, 95%CI = 52.5%-67.4%) of men during surgery immediately following foreskin removal. HIV shedding was detected in the post-surgical wound lavage at one or more follow-up visits in 41.3% of men (78/189). Compared to the pre-MC assessment, the probability of HIV shedding was significantly higher after MC at week one (17.9%, 30/186, 95%CI = 12.4%-24.5%), week two (30.2%, 49/162, 95%CI = 23.3%-37.9%) and week three (21.6%, 36/162, 95%CI = 15.5%-28.7%), and then declined at week four (6.5%, 11/168, 95%CI = 3.3%-11.4%) and week six (2.5%, 4/158, 95%CI = 0.7%-6.4%), Wilcoxon rank sum p<0.001. The median and interquartile range of log10 viral load among men with detectable viral shedding were: highest at week one (2.99, IQR = 2.59-3.45) and week two (3.20, IQR = 2.83-3.79), compared to week three (2.54, IQR = 2.27-2.94), week four (2.43, IQR = 2.24-3.73) and week six (2.46, IQR = 2.27-2.70). Plasma viral load did not change after MC and was not correlated with lavage viral load (r=0.07).

Conclusions: HIV shedding is increased from MC wounds, but returns to baseline approximately four weeks after surgery. Sexual abstinence and subsequent condom use are essential to reduce male-to-female HIV transmission following MC.
**Finding Unawares: High Levels of Undiagnosed HIV Infection Among Moscow Men Who Have Sex With Men**

Andrea L. Wirtz, Carla E. Zelaya, Noya Galai, Alena Peryshkina, Vladimir Moguilnyi, Petr Dzhigun, Irina Kostetskaya, Carl Latkin, Chris Beyrer

1Emergency Medicine, Johns Hopkins Medical Institute, Baltimore, MD, United States; 2Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD, United States; 3Epidemiology, Johns Hopkins School of Public Health, Johns Hopkins Medical Institute, Baltimore, MD, United States; 4AIDS Infoshare, Moscow, Russian Federation; 5Health, Behavior, and Society, Johns Hopkins School of Public Health, Baltimore, MD, United States

**Background:** Little is known about HIV testing behaviors of gay, bisexual and other MSM in Russia. Public sector testing is named based, and many MSM opt out of the system. New policies and laws may further restrict MSM from seeking HIV services. HIV prevalence, testing history, and correlates of undiagnosed HIV infection and risks were investigated in an anonymous MSM-friendly clinic in Moscow City.

**Methodology:** Participants were recruited via respondent driven sampling (RDS). Study activities included completion of an interviewer administered survey and biologic specimens for HIV testing. We examined the HIV testing/treatment cascade, socio-behavioral factors, and sexual identity characteristics. HIV prevalence was adjusted for participants’ network sizes. The proportion of previously undiagnosed HIV infections and correlates undiagnosed HIV infection were explored.

**Results:** 1433 MSM living in Moscow were recruited via RDS methods. Among this predominantly Russian born (85.0%), young population (median age 29 yrs.), most men self-identified as gay (55.0%) or bisexual (42.9%). Median age of first sex with a man was 18 years. Reported sexual risk practices in the last 12 months were high: 50.1% reported five or more anal sex partners (last 12mo.), 18.5% reported offering money/drugs in exchange for sex, 19.9% received money/drugs in exchange for sex, and 80.7% reported alcohol and/or drugs prior to sex. Men reported having only male partners (64.2%) or both male and female partners in the last 12mo. (35.1%). The majority of participants reported a lifetime history of HIV testing (85.5%) and 91.6% of those had received the result. The adjusted HIV prevalence among participants providing samples (n=1171) for HIV testing was 12.4 (95% CI: 9.3 - 16.1; unadjusted prevalence was 15.6%). Of participants testing positive or previously tested, 79.8% (n=146/183) had a previously undiagnosed HIV infection. Only 8.5% (16/189) of MSM with HIV infection were receiving ART. Among MSM living with HIV who self-identified as gay, 72.4% had undiagnosed infection, compared to 89.9% of bisexual men living with HIV infection (p=0.013).

**Conclusions:** This newly described population understands the importance of and utilizes HIV testing services, yet high risk practices and a high level of undiagnosed and untreated HIV infection persist. Moscow MSM will seek and use anonymous and safe HIV testing, and urgently need it. These findings have implications for public health programming and clinical care.

Laura A. Cooley, Alexandra M. Oster, Cyprian Wejnert, Binh C. Le, Charles E. Rose, Gabriela Paz-Bailey

Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States

**Background:** In 2010, 66% of new HIV infections in the United States occurred among men who have sex with men (MSM, including men who inject drugs); 35% of these MSM were black. HIV testing is an essential first step in HIV care and treatment for HIV-positive individuals. CDC began expanded HIV testing initiatives in 2007, focusing initially on blacks. A second focus, on MSM of all races, was added in 2010. We assessed changes in HIV testing behavior among MSM from 2008 to 2011.

**Methodology:** We analyzed data from the National HIV Behavioral Surveillance System. Men included in the analysis sample were recruited and interviewed in 2008 and 2011 at venues in 20 metropolitan statistical areas (MSAs), were ≥18 years old, reported at least one male sex partner in the past 12 months, and did not report a positive HIV test result more than 12 months prior to interview. We compared the proportions tested recently (past 12 months) from 2008 and 2011, using chi-square analysis, overall and by race/ethnicity. To determine if interview year was associated with recent HIV testing, we used a Poisson model with robust standard error to calculate adjusted prevalence ratios [APR] and 95% confidence intervals [CI]. The model was adjusted for race/ethnicity, age, education, income, and MSA; to see if temporal changes in recent HIV testing varied by race/ethnicity or age, we included interaction terms for interview year by race/ethnicity and age.
Results: We included 16,069 MSM (2008: 7,943; 2011: 8,126). In unadjusted analyses, recent testing increased from 63.3% in 2008 to 67.4% in 2011 overall ($P<0.001$) and from 63.0% to 70.9% among black MSM ($P<0.001$; see figure). MSM of other or multiple races also experienced an increase, from 63.1% to 75.1% ($P<0.001$). Model results indicated an overall increase in recent testing (APR=1.09, CI=1.06-1.12) and that the increase varied significantly by race/ethnicity (the interaction of year with age was not significant). Increases were largest for black MSM (APR=1.12, CI=1.07-1.17) and MSM of other or multiple races (APR=1.20, CI=1.11-1.30). The proportions tested did not change significantly for Latino MSM (APR=1.02, CI=0.98-1.08) or white MSM (APR=1.03, CI=0.98-1.07).

Conclusions: HIV testing increased among black MSM and MSM of other or multiple races from 2008 to 2011. Despite gains in testing, improved coverage is still needed, consistent with CDC recommendations. Increasing the number of MSM tested and linked to care will improve health outcomes and may reduce transmission of HIV.

969 Feasibility of HIV Self-Test Vouchers To Raise Community-Level Serostatus Awareness, Los Angeles
Robert Marlin1, Sean Young1, Greg Wilson2, Jeffrey P. Rodriguez3, Jose Ortiz4, Rhea Mathew5, Zoe Glick6, Jeffrey D. Klausner1
1David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, United States, 2Reach LA, Los Angeles, CA, United States, 3LA Gay & Lesbian Center, Los Angeles, CA, United States, 4Bienestar, Los Angeles, CA, United States, 5University of California Los Angeles, Los Angeles, CA, United States, 6Brentwood School, Los Angeles, CA, United States

Background: About 25% of HIV-infected individuals are unaware of their status and may cause up to half of all new HIV cases. In particular, men who have sex with men (MSM) and minorities are at high risk for being sero-unaware and would benefit from increased testing. The FDA recently approved the OraQuick® In-Home HIV Test, a new method to increase HIV serostatus awareness and testing. While past studies show that the test is highly acceptable, none have determined how to best promote it to high-risk groups. We examined the feasibility of implementing a voucher program for free OraQuick® In-Home HIV Test kits targeting high-risk MSM in Los Angeles.

Methodology: The following measures were used to determine feasibility: (1) the creation of a user-friendly voucher describing the OraQuick® test and where and how to redeem the voucher, (2) the establishment of a redemption and third-party payment system with a retail location, (3) the formation of relationships with community based organizations (CBOs) and other groups for dissemination, and (4) the use of social media such as Facebook® to promote the voucher. In addition, we determined the feasibility of recruiting and enrolling voucher users for interviews by: (1) the attachment of a survey recruitment flyer to the voucher, (2) the establishment of an anonymous call-in survey system, and (3) the willingness of voucher users to answer questions on their HIV testing behaviors and results. Analyses were done with Microsoft Excel® to calculate descriptive statistics and Facebook Ads Manager® to measure Facebook® use.

Results: We created a paper voucher for free OraQuick® kits and partnered with Walgreens® to develop a trackable redemption and payment system. Walgreens was chosen as a retail partner based on the location of its stores. Our Facebook® ads reached 28,910 users from July 25 through September 27 2013. Between July 19 and October 8 2013, we supplied 641 vouchers to 3 CBOs, 3 student distributors, and one clinic. Distributors reported dispensing 196 (30.6%) of the 641 supplied vouchers to clients and 44 (22.4%) clients redeemed their vouchers. Twenty-eight (63.6%) of the 44 who redeemed their vouchers participated in our survey, one of whom newly tested HIV-positive and was linked to care.

Conclusions: Our findings suggest that the development of a voucher system to promote HIV self-testing kits is feasible. It is also feasible to track voucher use, collect information anonymously from voucher users, and identify new HIV cases. Our methods could be used to assess whether a self-testing promotion system enhances the community level of serostatus awareness. Continued work should be done to expand the voucher program and compare it with other methods of self-testing promotion and traditional HIV testing.
Availability, Accessibility, Price of Rapid HIV Self-Tests, New York City Pharmacies, Summer 2013

Julie E. Myers1, 2, Olivia El-Sadr Davis3, Elliott R. Weinstein4, Molly Remch5, Amy L. Edelstein6, Blayne H. Cutler1, Julia A. Schillinger1, 6
1Bureau of HIV/AIDS Prevention and Control, New York City Department of Health and Mental Hygiene, Queens, NY, United States, 2Department of Medicine, Division of Infectious Diseases, Columbia University Medical Center, New York, NY, United States, 3Health Research Training Program, New York City Department of Health and Mental Hygiene, Queens, NY, United States, 4New York Medical College, Valhalla, NY, United States, 5Bureau of STD Prevention and Control, New York City Department of Health and Mental Hygiene, Queens, NY, United States, 6Division of STD Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States

Background: The US FDA recently approved an over-the-counter, rapid HIV self-test for personal use. Since October 2012, kits have been available in US pharmacies (manufacturer’s suggested retail price, or MSRP, $39.99). We conducted a survey of NYC pharmacies to assess the availability, accessibility, and price of rapid HIV self-tests.

Methodology: All NYC pharmacies (n=2568) were stratified into tertiles using the HIV diagnosis rate of the neighborhood in which the pharmacy was located using surveillance data. A random sample of 250 pharmacies was taken from the first (high morbidity neighborhood [HighMN]) and third (low morbidity neighborhood [LowMN]) tertiles, since we were primarily interested in disparities in neighborhood access to the self-test kit associated with the burden of new HIV infections. Pharmacies were excluded if: closed during business hours, non-retail, or >10 minute walk from a subway station (except for Staten Island) by online mapping. Project staff visited the pharmacy, observed whether it was an independent or major chain pharmacy (>50 locations in NYC), asked a pharmacist/photograph technician about the kit’s availability/location, visually inspected the pharmacy for kits, and determined price. Handheld devices were used for data collection. We conducted bivariate analyses using the chi-square test for dichotomous variables and the t-test for continuous variables.

Results: There were 361 pharmacies in the final sample (161 from LowMN and 200 from HighMN). Overall, kits were available in 27% of pharmacies [30% of LowMN and 24% of HighMN (p=0.13)]. Kits were available in 84% of chain pharmacies (which made up only 24% of pharmacies surveyed) compared to only 9% of independent pharmacies (p<0.01). There was no difference in aisle display location, but kits were more often kept behind the pharmacy counter in HighMN (77%) vs. LowMN (55%, P<0.03). In pharmacies that had kits available (n=97), 80% of pharmacists correctly stated kit availability, and 88% of those pharmacists correctly identified ≥1 kit location. Median kit price was US$42.99 (range: US$32.99-50.00); 66% of pharmacies set kit price above MSRP. There was no price difference by neighborhood tertile.

Conclusions: Approximately 1 year after FDA approval, rapid HIV self-test kits were available in less than a third of pharmacies in LowMN and HighMN in NYC but in most chain pharmacies. Pharmacies in areas of greatest need for HIV prevention were more likely to require interaction with the pharmacist to obtain the kit - a potential obstacle to purchase. Price was often set above MSRP and did not differ by neighborhood disease burden. To make the self-test kit a viable method for low-threshold testing in HighMN, efforts are needed to encourage more pharmacies to carry them and display them more openly.

Acceptability & Affordability of Self HIV Testing in an Urban Neighborhood With 3% Seroprevalence

Amy Nunn1, Philip Chan1, Caitlin Towey1, Joanna Poceta1, Sophie Feller1, Stacey Trooksin1
1Division of Infectious Diseases, Warren Alpert Medical School of Brown University, Providence, RI, United States, 2Jefferson Medical Collage, Philadelphia, PA, United States, 3Drexel University College of Medicine, Philadelphia, PA, United States

Background: The USFDA recently approved the “OraQuick® In-Home HIV Test,” the first over-the-counter self test for HIV, which retails for approximately US $40. Little is known about the self test’s acceptability, accessibility and affordability in the United States’ most heavily impacted neighborhoods and among individuals at highest risk for acquiring HIV.

Methodology: We explored acceptability, accessibility and affordability of self testing among 994 community residents participating in a community-based HIV and HCV testing, treatment and linkage to care program called “Do One Thing”. Do One Thing takes place in a Philadelphia zip code with 3% HIV infection; 39% were uninsured, 56% lived below the poverty line, and 37% had incarceration histories. Participants had very positive attitudes about self HIV testing, including willingness to use and pay for self tests, and whether individuals would seek medical care if they were to test positive.

Results: HIV seropositivity among this population was 1.2%. Participants reported high-risk behaviors; 23% were engaged in concurrent sexual partnerships, 24% believed their partners were engaged in concurrent partnerships and 15% reported injection drug use or cocaine use. Eleven percent were men who have sex with men and 88% were African American. Participants also reported socioeconomic factors frequently correlated with HIV infection; 39% were uninsured, 56% lived below the poverty line, and 37% had incarceration histories. Participants had very positive attitudes about self HIV testing and linkage to care (Figure 1). The overwhelming majority was willing to self test (91%) and also believed their families, friends or loved ones would be willing to self test (78%). Almost all participants reported they would seek medical care if they were to test HIV-positive (96%). Although most were willing to pay for the test (57%), only 26% of participants were willing to pay more than $20 and only 14% were willing to pay the current market price.

Conclusions: Self-testing was highly acceptable in this neighborhood with high rates of HIV infection and most respondents reported they would seek medical care if they tested positive. The self test is an important tool for expanding access to testing in heavily impacted neighborhoods but its price may be prohibitively expensive for the highest risk populations. Public health programs should consider financing self-testing and linkage to care programs in heavily impacted neighborhoods.
Figure 1. Attitudes about self HIV testing in a Philadelphia neighborhood with high rates of HIV infection (N=994)

Getting To Zero: HIV Testing and Counselling in Kenya - Results From a Population-Based Survey
Anne Nganga1, Wanjiru Waruiru1, Carol Ngaro2, Victor Ssempijja3, Patricia Oluoch4, Thomas Sachuki5, William Maina6, Rex Mpazanje7, Andrea A. Kim2

Background: HIV testing and counselling (HTC) is a gateway into HIV prevention and treatment programs. In 2007, only 36% of persons had ever been tested for HIV. The universal access target for HIV testing in is 80% of the population. Nationally-representative data on HIV testing are important to evaluate Kenya’s progress towards reaching the universal target.

Methodology: In 2012, Kenya conducted a national household survey among persons aged 18 months-64 years. Respondents aged 15-64 years were administered a questionnaire and provided blood for centralized testing. Home-based testing and counselling (HBTC), using rapid HIV testing kits based on the national HIV testing algorithm was offered to participants to learn their HIV status. Point-of-care CD4 T-cell count testing was conducted among persons testing HIV+ in HBTC. Data were weighted to account for sampling probability and adjusted for for non-response. We describe HIV testing among survey respondents aged 15-64 years. Results from HBTC are based on a subset of participants that accepted HBTC.

Results: Of 13,720 adults interviewed, 71.6% (80.4% women, 62.5% men) had ever been tested for HIV. Among those, 56.1% had been tested in the past year, 69.3% had been tested more than once, and 37.2% had been tested with a sexual partner. Fifty-three percent of HIV-infected persons did not have correct knowledge of their HIV status. Incorrect knowledge of HIV positive status was higher among men [62.0%; 95% confidence interval (CI) 53.4-70.5] compared to women [47.8%; 95% CI 42.1-53.4], youth aged 15-24 years [81.0%; 95% CI 72.3-91.7] compared to persons aged 25-34 years [58.9%; 95% CI 50.5-67.4], and persons who did not use condoms with their most recent sexual partner in the past 12 months [67.7%; 95% CI 60.3-75.1 vs. 37.1%; 95% CI 29.1-45.2]. Overall, 9,874 (72.0%) participants accepted HBTC. Among those, 361 (4.1%; 95% CI 3.3-4.9) tested HIV+, and of those, 94% accepted POC CD4+ T-cell count testing. Of those, the median CD4+ T-cell count was 423 cells/mm3 (interquartile range: 250-573), and 40.3% (95% CI 30.8-49.6) of those who were antiretroviral therapy (ART) naive were eligible for ART based on current national guidelines (CD4<350 cells/mm3).

Conclusions: HIV testing has improved over the last five years, nearly reaching the universal access target in Kenya. However, correct knowledge of HIV status among HIV-infected persons remains low. HTC should be expanded to reach more men and youth, and strategies are needed to increase repeat testing for persons at risk. HBTC for HIV can be successfully integrated into population-based surveys as a tool to identify persons in need of treatment. However, HIV prevalence data from HBTC will be an under-representation of national prevalence due to selective participation.

Counselor Based Versus Integrated Routine HIV Screening in an Urban Emergency Department
Georgina Osorio1, Anca Giurgiulescu1, Zacharias Hennessey2, Andrea Wood2, Daniel Egan3, Dan Wiener2, Rituparna Pati1, Victoria Sharp1
1Medicine, Spencer Cox Center for Health, St. Luke’s-Roosevelt Hospital Center, New York, NY, United States, 2Emergency Medicine, St. Luke’s-Roosevelt Hospital Center, New York, NY, United States, 3Emergency Department, New York University School of Medicine, New York, NY, United States

Background: Since 2006, St. Luke’s-Roosevelt (SLR) Hospital has offered Emergency Department (ED) patients free HIV testing. Starting in July 2010, the Spencer Cox Center for Health partnered with the ED to move from a counselor-based to a routine, integrated model of oral rapid HIV testing in the hospital’s two EDs in New York City (NYC). Under this integrated model and in compliance with the 2010 New York State (NYS) HIV Testing Law, all ED patients aged 13-64 years old were routinely offered rapid HIV testing at triage; and result notification, counseling, and testing was performed by teams of medical providers and nursing. The aim of this study is to describe the demographic population profile of patients who underwent HIV rapid testing and to analyze any significant differences in the populations reached by HIV testing in the ED before and after the implementation of routine HIV testing.

Methodology: Data was collected from 5/2006 to 6/2013 of all adolescent and adult patients who underwent HIV rapid testing (RT) unless they declined or were ineligible [Level I or II trauma, <13 years old]. After verbal consent, HIV testing (OraQuick® Advance Rapid HIV-1/2 Antibody test) was performed. Confirmatory labs were performed following preliminary positive results. All demographic characteristics of patients who underwent HIV testing between 5/2006-6/2010 (counselor-based) were compared to those patients testing between 7/2010-6/2013 (routine testing), using Fisher Exact and Wilcoxon tests. Factors associated with testing positive on the rapid oral test were analyzed in multivariate logistic regression.

Results: 48274 HIV tests were conducted. Majority of patients were female (54%; N=26216) and insured (71%; N=34371) with a median age of 34 yrs (range=13-99 yrs). 87% of testing occurred during the routine testing period (N=42198), showing a 7-fold increase in testing volume after transition to an integrated model (1,453 in 2009 vs 11,443 in 2010). There were no significant differences in race, gender, insurance status, and age between patients who underwent HIV testing in the ED using the both models. 328 (0.7%) patients tested HIV positive; 258 (79%) during the routine testing period. In multivariate analysis, significant predictors of testing HIV positive were male gender (p<0.001), Medicaid (p<0.001), uninsured (p<0.001), Hispanic (p=0.018), and Black (p<0.001).

Conclusions: Routine HIV testing in the ED was feasible and allowed for significant increases in patient access to HIV testing and in identification of HIV infections. Patients who tested HIV positive were more likely to be male, uninsured, and non-White; highlighting the importance of having free and routine HIV testing in the EDs of large urban hospital centers.
974 Low Feasibility Rate of Self Testing With a Finger-Stick Whole Blood Test
Guillaume Gras1, Pascal Le Bret2, Jean Francois Dalloix2, Gwenaël Le Moal3, Aurelia Raoult4, Gaelle Fajole5, Penelope Hodges6, Claire Poirier1, Frédéric Bastides1, Louis Bernard1
1Infectious Diseases, CHU Bretonneau, Tours, France, 2Infectious Diseases, Reseau VIH 37, Tours, France, 3Infectious Diseases, CHU, Poitiers, France, 4Pharmacie, CHU Bretonneau, Tours, France, 5COREVIH, CHU Bretonneau, Tours, France

Background: Self HIV testing would contribute measurably to public health by helping more infected individuals become aware of their HIV status and therefore reducing HIV transmission. In 2012, the FDA approved the OraQuick In-Home test with oral (saliva) swab. INSTI HIV1/HIV2®, a finger-stick whole blood test, used for years by healthcare professionals, more sensitive, provides a test result in 5 minutes and could be an alternative. Little is known about the feasibility of self-testing with finger-stick whole blood tests.

Methodology: We conducted a prospective monocentric study (September 2013). Eligibility requirements included: > 18, HIV positive patient without mental or physical handicap. After agreement, patients performed self testing with INSTI HIV1/HIV2® with a detailed notice. The test was considered as correct if patient performed all steps alone with a correct interpretation of the results.

Results: Forty patients (mean age = 45.8, sex ratio M/F = 3.4) were included with primary education (13), secondary education (14), tertiary education (13). Viral load was < 1,6 log for 25 patients (62.5%). Five (12.5%) patients did not able to complete all steps of the test. Of the remaining 35 HIV positive patients, 25 had a positive test result (sensitivity=71.4%), 1 negative (patient with undetectable viral load), 2 invalid, 7 non-reactive. Mean time to perform testing was 6 minutes 40 s (min = 3 min 20 s, max = 13 min 30 s): mean time for blood collection = 3 min 50 s and for mixing and reading = 3 min 20 s. The test was correctly performed by 19 patients (47.5%). Main reasons for failure were lack of blood (11), wrong lancet utilization (4), and in the mixing of the samples (3). Factors associated with success were: age (40.4 vs 50.8, p = 0.02) and tertiary education (53% vs 14%, p = 0.01). The pain was low for 21 (52.5%) patients and 19 (47.5%) patients declared no pain. The notice was considered as adapted for 27 patients and relatively adapted for 13. Performing the test was considered very easy for 22 patients and quiet easy for 18. Thirty four (85%) patients would recommend this test to a friend. Because of low rate of feasibility, the study was stopped.

Conclusions: Feasibility of self testing with INSTI VIH1/VIH2® appears to be low in our study. The main reason for failure was blood collection. However a finger-stick whole blood test does not appear to be a barrier to self testing. An improvement in the technique of whole blood collection should be made.

975 Estimating the Size of the Undiagnosed HIV Population in the Netherlands by Disease Stage
Ard van Sighem1, Fumiyo Nakagawa2, Daniela Bezemer1, Daniela De Angelis3, Eline Op de Coul4, Matthias Egger5, Frank de Wolf6, Christophe Fraser6, Andrew Phillips2
1Stichting HIV Monitoring, Amsterdam, Netherlands, 2University College London, London, United Kingdom, 3MRC Biostatistics Unit, Cambridge, United Kingdom, 4National Institute for Public Health and the Environment, Bilthoven, Netherlands, 5University of Bern, Bern, Switzerland, 6Imperial College School of Medicine, London, United Kingdom

Background: Previous studies showed that a large proportion of HIV-infected individuals in the Netherlands are unaware of their infection. As recent estimates of the size of this group are not available, we sought to estimate the number and proportion of undiagnosed individuals stratified by risk group and by CD4 cell count stratum.

Methodology: Using a newly developed adaptation of a previously published back-calculation method, we estimated the annual number of new HIV infections over calendar time as well as CD4 count stratum-specific rates of diagnosis by fitting a model of disease progression to observed data from the ATHENA national observational HIV cohort on HIV and AIDS diagnoses and CD4 counts at the time of diagnosis. The model incorporated different stages of HIV infection characterised by CD4 counts and described disease progression in the absence of antiretroviral treatment from the time of infection to HIV diagnosis or onset of AIDS. Rates of progression between the different disease stages were based on historical cohort data on untreated HIV-infected patients. We considered men who have sex with men (MSM), injection drug users (IDU), and heterosexual men (HET-M) and women (HET-W) originating from the Netherlands, i.e., groups consisting mostly of non-migrants. Bootstrap techniques were used to calculate 95% confidence intervals (CI).

Results: By the end of 2011, a cumulative number of 19,761 HIV infections - 15,152 in MSM, 1170 in IDU, 1189 in HET-W, and 2250 in HET-M - were estimated to have occurred since the start of the epidemic in the 1980s (see Table). Altogether, 2938 (15%) of all infections were still undiagnosed: 2207 (15%) MSM, 16 (1%) IDU, 134 (11%) HET-W, and 581 (26%) HET-M. Amongst the undiagnosed individuals, 1142 (52%) MSM, 4 (28%) IDU, 53 (40%) HET-W, and 240 (41%) HET-M were estimated to have a CD4 cell count ≥ 500 cells/mm³. The number of undiagnosed individuals with CD4 counts below 350 cells/mm³ was 600 (27%) for MSM, 8 (51%) for IDU, 51 (38%) for HET-W, and 217 (37%) for HET-M.

Conclusions: Although MSM formed the largest group of HIV-infected individuals unaware of their infection, the estimated CD4 distribution suggested that approximately half of them were in an early stage of infection and had been infected only recently. Approximately 30% of the undiagnosed individuals were already in immediate need of treatment. This proportion was even higher in groups other than MSM although absolute numbers of undiagnosed individuals in these groups were much smaller.
Christine E. Ross, Guoyu Tao, Karen W. Hoover
DSTDP, CDC, Atlanta, GA, United States

Background: Prenatal screening for maternal HIV infection is a critical step in the prevention of mother-to-child transmission of HIV. The U.S. Centers for Disease Control and Prevention (CDC) recommends universal HIV screening of all pregnant women, and since 2006, has recommended an opt-out model to increase HIV testing uptake and coverage. CDC also recommends universal prenatal screening for syphilis and hepatitis B. We estimated prenatal testing coverage for syphilis, hepatitis B, and HIV in a large Medicaid-insured population in the United States during 2009–2010.

Methodology: We analyzed Medicaid claims data from a large administrative database to estimate testing coverage for syphilis, hepatitis B, and HIV among pregnant women aged 15–44 by age group and by race and ethnicity. We used procedural and diagnostic codes to identify pregnant women with a live birth in 2010, and included those who were continuously enrolled in Medicaid ≥210 days prior to the date of delivery. Procedural codes were used to identify syphilis.hepatitis B, and HIV screening tests, and Rh and ABO blood typing. Maternal blood typing is performed as part of routine obstetric care and was used to estimate the proportion of women who had received prenatal care.

Results: Among 113,943 pregnant women, 87% (98,709) had claims for Rh and ABO blood typing. Among women with Rh and ABO blood typing, 98% (96,735) were tested for syphilis, 97% (95,748) for hepatitis B, and 84% (82,916) for HIV. Prenatal testing coverage for all three diseases decreased with age. The greatest difference in testing coverage by age was observed for HIV: it was 87% for women 15–19 years and 79% for women >35 years. Testing coverage for syphilis was 92% for Hispanic women, 98% for white women, and 100% for black women; for hepatitis B it was 91% for Hispanic women, 97% for white women, and 98% for black women. HIV testing coverage did not differ by race and ethnicity.

Conclusions: Among women with Rh and ABO blood typing, prenatal testing for syphilis and hepatitis B was nearly universal. However, prenatal testing for HIV was suboptimal, indicating that barriers to HIV testing still exist. Interventions are needed to facilitate the routinization of prenatal HIV testing.

977  Measuring Late HIV Diagnosis Among Men Who Have Sex With Men: AIDS Diagnosis vs. Testing Frequency
David A. Katz1,2, Julia C. Dombrowski1, Amy Bennett2, Susan Buskin2, Christina Thibault2, Matthew R. Golden1
1University of Washington, Seattle, WA, United States, 2Public Health - Seattle & King County, Seattle, WA, United States

Background: HIV surveillance in the U.S. monitors the occurrence of AIDS within one year of HIV diagnosis as a surrogate measure for late HIV diagnosis. The validity of this approach, particularly in populations with high levels of testing, is uncertain.

Methodology: We examined the relationship between AIDS diagnosis within 1 year of HIV diagnosis and time from last negative to first positive HIV test (intertest interval, ITI) using HIV surveillance and partner services data. Public health staff routinely assessed dates of last negative tests through partner services interviews or medical record review. We categorized ITIs as ≤12, 13–24, 25–36, 37–48, 49–60, >60 months, or never tested, then calculated the proportion of AIDS ≤1 year from HIV diagnosis within each ITI category (ITI AIDS risk). We modeled hypothetical changes in population-level testing frequency by sequentially moving 50% of persons in each ITI category into the next higher or lower category. For each new distribution of ITIs, we estimated the proportion of persons with AIDS ≤1 year from HIV diagnosis by applying our ITI AIDS risk data. When calculating median ITIs, men who never tested negative were assigned the maximum observed ITI.
Results: From 1/1/2010-8/30/2012, 583 cases of HIV were diagnosed among MSM in King County, WA. Among 547 (94%) MSM with testing history data, the median ITI was 16 months (IQR: 6-48), and 326 (60%) and 430 (79%) had tested within 2 and 5 years of diagnosis, respectively. 138 (25%) were diagnosed with AIDS within 1 year of HIV diagnosis, of whom 40 (29%) and 81 (59%) had tested within 2 and 5 years of HIV diagnosis, respectively. The figure shows estimates of the proportion of MSM diagnosed with AIDS within 1 year of HIV diagnosis at varying population testing frequencies. Decreasing the median ITI from 16 to 9 months - which involves 58% of newly diagnosed MSM testing negative ≤1 year prior to diagnosis - decreased the proportion of AIDS ≤1 year after HIV diagnosis from 25 to 19%. Increasing the median ITI to 31 months increased this proportion to 31%.

Conclusions: Population estimates and individual-level classification of late HIV diagnosis differed based on how late diagnosis was defined. Even large changes in HIV testing frequency among MSM may have limited impact on the proportion of persons with AIDS within 1 year of HIV diagnosis, suggesting that the measure may have limited utility in monitoring the success of HIV case-finding efforts. Efforts to monitor trends in late diagnosis should include the ITI.

Cascade of Care, Linkage, and Retention

978 Using HIV Surveillance Registry Data To Re-Link Patients To Care: The RSVP Project in San Francisco
Kate A. Buchacz1, Miao-Jung Chen2, Maree Kay Parisi2, Maya Yoshida2, Erin Antunez2, Viva Delgado2, Nicholas J. Moss3, Susan Scheer2
1Centers for Disease Control and Prevention, Atlanta, GA, United States, 2San Francisco Department of Public Health, San Francisco, CA, United States, 3Alameda County Public Health Department, Oakland, CA, United States

Background: Patients with unsuppressed HIV viral load (VL) who fall out of care may experience poor clinical outcomes and potentially transmit HIV. We assessed the feasibility and yield of using the San Francisco Department of Public Health (SFDPH) enhanced HIV surveillance system (eHARS) to identify such persons and re-engage them in care.

Methodology: Using SFDPH eHARS data as of 4/20/2012, we selected HIV-infected adults who had a VL >200 copies/mL in blood samples drawn 9-15 months earlier and had no subsequent reported VL or CD4 laboratory results (a proxy for being "out-of-care"). We prioritized cases presumed alive and residing in the Greater San Francisco Bay Area (GBA) for outreach. We used information from eHARS and medical and public health databases to contact cases for interview and referral to the SFDPH linkage services (LINCS). We then repeated our original eHARS case selection through 4/20/2012, this time matching with eHARS data current as of 4/20/2013, to assess how reporting delays of HIV laboratory results affected original eligibility, and what percentage of cases had any subsequent HIV laboratory results reported between 4/20/2012 and 4/20/2013.

Results: Of 476 selected cases, 42 (9%) were deceased and 152 (32%) were living outside the GBA per SFDPH eHARS on 4/20/2012. Among the remaining 282 cases, after extensive search and outreach efforts, 75 (27%) were interviewed (Figure). Fifty-eight (77%) of these cases reported seeing an HIV provider in the prior year and 54 (72%) accepted referral to LINCS. Of those referred, 28 needed re-linkage and 26 accepted other services. Re-running our original match one year later, of the 282 cases originally prioritized for outreach, 213 (76%) still met the original eligibility criteria, of whom 130 (61%) had a subsequent reported HIV laboratory result between 4/20/2012 and 4/20/2013. Delayed HIV laboratory reporting from counties outside of SF was the most common reason cases were re-classified as ineligible when we repeated the original match one year later.

Conclusions: Among HIV cases identified as out-of-care and prioritized for RSVP outreach, about one-quarter were interviewed and offered re-linkage to HIV care, demonstrating the feasibility but limited yield of our project. Most patients had some HIV care regardless of contact through the RSVP Project. Verifying patients' HIV care status with medical providers and improving HIV laboratory reporting mechanisms may aid future similar efforts.
**Disentangling Roles of Internalized Stigma and Depression in Women's Linkage To Care**

Kristi L. Stringer, Bulent Turan, Maricianah Onono, Elizabeth A. Bukusi, Craig C. Cohen, Janet M. Turan

1. Medical Sociology, University of Alabama at Birmingham, Birmingham, AL, United States
2. Psychology, University of Alabama at Birmingham, Birmingham, AL, United States
3. Kenya Medical Research Institute, Nairobi, Kenya
4. Department of Obstetrics, Gynecology, and Reproductive Sciences, University of California San Francisco, San Francisco, CA, United States
5. Medical Health Care Organization and Policy, University of Alabama at Birmingham, Birmingham, AL, United States

**Background:** Linkage of HIV-positive pregnant and postpartum women to HIV care and treatment programs is essential for long-lasting maternal and child health. Internalized HIV-related stigma, defined as self-devaluation and/or shame due to one’s HIV status, has been suggested as an important barrier to engagement in HIV care. However, it remains unclear if the effect of stigma is mainly due to depression, which is also an impediment to use of health services and is highly correlated with internalized stigma. In order to understand how to support women’s linkage to HIV care, it is crucial that we disentangle the unique roles of stigma and depression.

**Methodology:** Women were recruited at nine antenatal clinics in Kenya. Of 239 pregnant women newly diagnosed with HIV and interviewed during pregnancy, 165 (70%) participated in follow-up interviews six weeks after delivery. Data on women’s linkage to HIV care during the follow-up period were obtained from medical records. We examined relationships between a measure of internalized stigma, postnatal depression scores (Edinburgh Postnatal Depression Scale, EPDS), and linkage to HIV care using logistic regression, accounting for clustering by clinic.

**Results:** Six weeks after delivery only 56% of the women had linked with HIV care. Of the women who participated in follow-up interviews, half reported experiencing internalized HIV-related stigma, and 23% had an EPDS score ≥13 indicating depression. Those who reported any internalized stigma had significantly higher odds of depression (OR=4.10, 95%CI=1.70-9.92). In bivariable analyses, internalized stigma was significantly associated with reduced odds of linkage to care (OR=0.56, 95%CI=0.38-0.82) and depression was marginally significant (OR=0.46, 95%CI=0.19-1.13). After adjusting for depression and other predictors, internalized stigma remained significantly associated with reduced linkage to care (adjusted OR=0.56, 95%CI=0.35-0.88), while postnatal depression was not (p=0.63).

**Conclusions:** Our results suggest that HIV-related stigma and depression have negative effects on linkage to HIV care among pregnant and postpartum women, and that stigma has a significant effect independent of depression. These findings indicate that in addition to depression interventions, services for this population need to incorporate specific HIV-related stigma reduction and coping strategies.

**Longitudinal Treatment Outcomes in HIV-Infected Prisoners and Influence of Re-Incarceration**

Jaimie P. Meyer, Javier Cepeda, Johnny Wu, Robert L. Trestman, Frederick L. Altice, Sandra A. Springer

1. Medicine, Yale University School of Medicine, New Haven, CT, United States
2. Chronic Disease Epidemiology, Yale University School of Public Health, New Haven, CT, United States
3. Epidemiology of Microbial Diseases, Yale University School of Public Health, New Haven, CT, United States
4. University of Connecticut Correctional Managed Healthcare, Farmington, CT, United States

**Background:** One-sixth of PLWHA transition through prison or jail annually but treatment outcomes during and following incarceration have not been systematically evaluated in over a decade.

**Methodology:** A retrospective cohort study of HIV+ prisoners on ART (2005-2012) examined treatment outcomes using longitudinally linked correctional, pharmacy, and laboratory databases. Viral suppression (VS) on release, defined as HIV-1 RNA<400, was the primary outcome; secondary outcomes were
mean change in log-transformed HIV-1 RNA and CD4 count during incarceration. Correctional characteristics, ART type, directly observed therapy (DOT), and other characteristics were analyzed as correlates of VS. In a sub-sample of recidivists with ≥90 days in the community, we examined VS on reentry.

**Results:** Among 882 HIV+ prisoners (1,185 incarceration periods), proportion achieving VS was significantly higher on release compared to entry (70.0% vs 29.8%; p<0.001). VS on release correlated with female gender (AOR=1.81, 95%CI 1.26-2.59) and lower psychiatric severity (AOR=1.50, 95%CI 1.12-1.99), but not race/ethnicity, incarceration duration, ART regimen type, or DOT. During incarceration, only 36.8% of prisoners switched ART regimen, primarily from nRTI- to PI-based regimens. For 497 recidivists (934 incarceration periods), after a median 329 days in the community, VS was significantly lower than on last release (31.3% vs. 52.2%; p<0.001). VS on reentry correlated with increasing age (AOR=1.04, 95%CI 1.02-1.07), receiving an nRTI based regimen (AOR=1.93, 95%CI 1.42-2.63) or being prescribed an antidepressant (AOR=1.40, 95%CI 1.01-1.95), and negatively with being Black (AOR=0.66, 95%CI 0.45-0.98).

**Conclusions:** From the largest contemporary systematic evaluation of HIV treatment outcomes among prisoners on ART, the majority achieved VS, confirming that ART can be optimized during incarceration when appropriate resources are provided. Compared to an earlier cohort (1997-2002), more achieved VS on release with fewer ART changes and VS was more often sustained through reentry, likely due to ART regimens with lower pill burden and fewer adverse side effects. The decrease in VS between release and reentry suggests that more effective transitional care and services are still needed to improve individual and societal health and reduce onward HIV transmission post-release.

981 **Imprisonment Among a Large US Clinical Cohort of HIV-Positive Outpatients**

David L. Rosen1, Carol E. Golin2, Catherine A. Grodensky3, Samuel Stinnett4, Becky L. White4, Sonia Napravnik5, David A. Wohl6

1Institute for Global Health and Infectious Diseases, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 2Medicine and Health Behavior, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 3Center for AIDS Research, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 4Division of Infectious Diseases, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

**Background:** Retention in HIV care is critical to good outcomes but can be interrupted by incarceration: an estimated 14% of all HIV-positive (HIV+) individuals in the US pass through a prison or jail annually. A greater understanding of the characteristics of HIV+ patients who become incarcerated and the resulting lapse in clinical care between community and correctional settings could inform interventions to improve their health outcomes and reduce transmission.

**Methodology:** We deterministically matched and linked records from the UNC Center for AIDS Research HIV Clinical Cohort (UCHCC) with records from the NC state prison system. For January 2000 to May 2011, we examined the proportion of UCHCC patients who became imprisoned, UNC clinic visits prior to imprisonment, the time lapse between clinical care and prison entry, most recent viral load (VL) prior to incarceration, and the covariate-adjusted associations between patient demographic and clinical characteristics and a subsequent incarceration.

**Results:** From January 2000 to May 2011, 3,258 UCHCC patients attended at least one clinical HIV visit; 71.1% male. 70.6% non-White. During the same period, 5.2% (n=170) were imprisoned a total of 180 times. The median time of follow-up at UNC prior to imprisonment, number of HIV clinic visits before incarceration, and time from last UNC visit to prison entry were, respectively, 1.5 (inter-quartile range [IQR] 0.1-3.8) years, 5 (IQR: 2-14) visits, and 11.7 (IQR: 3.4 - 32.9) months. For 63% (n=106), the most recent VL prior to imprisonment was detectable (i.e. ≥400 copies/mL). Injection drug use history, ≥80% adherence, and DOT were associated with being Black (AOR=0.66, 95%CI 0.45-0.98). Injection drug use history, injection drug use history, ≥80% adherence, and DOT were associated with being Black (AOR=0.66, 95%CI 0.45-0.98). Injection drug use history, injection drug use history, ≥80% adherence, and DOT were associated with being Black (AOR=0.66, 95%CI 0.45-0.98). Injection drug use history, injection drug use history, ≥80% adherence, and DOT were associated with being Black (AOR=0.66, 95%CI 0.45-0.98). Injection drug use history, injection drug use history, ≥80% adherence, and DOT were associated with being Black (AOR=0.66, 95%CI 0.45-0.98). Injection drug use history, injection drug use history, ≥80% adherence, and DOT were associated with being Black (AOR=0.66, 95%CI 0.45-0.98).

**Conclusions:** In a large outpatient HIV+ cohort of patients, one in twenty were imprisoned. For nearly half of those who became incarcerated the period between last clinic visit and prison entry was over a year, many of these patients are out of care and at risk for HIV transmission and poor health outcomes. However, these patients had a high frequency of visits prior to imprisonment. These results highlight the individual and clinical factors associated with risk of incarceration and opportunities to detect and intervene prior to imprisonment.
Beyond Core Indicators of Retention in HIV Care: Added Prognostic Value of Missed Clinic Visits

Michael J. Mugavero¹, Andrew O. Westfall¹, Elvin Geng², Stephen R. Cole², Heidi M. Crane³, Mari M. Kitahata³, W. Christopher Mathews⁴, Sonia Napravnik⁵, James L. Raper¹, CFAR Network of Integrated Clinical Systems (CNICS)
¹Medicine, University of Alabama at Birmingham, Birmingham, AL, United States; ²Medicine, University of California San Francisco, San Francisco, CA, United States; ³Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; ⁴Medicine, University of Washington, Seattle, WA, United States; ⁵Medicine, University of California San Diego, La Jolla, CA, United States

Background: The Institute of Medicine (IOM) and Department of Health and Human Services (DHHS) have released core indicators of retention in HIV care calculated based upon attended clinic visits (2 visits at defined intervals per 12 month period). Recent research suggests missed clinic visits may capture distinct aspects of retention from measures based upon attended visits. We evaluated associations between the IOM and DHHS retention measures and all-cause mortality, and further assessed the added prognostic value of missed visits when used in conjunction with these core indicators.

Methodology: HIV-infected patients initiating ART at 5 CNICS sites from 2000-11 were included. Retention in care over 24-months (mos) following ART start was measured using the IOM (HRSA HAB measure) and DHHS core indicators, and as a count of missed (no show) clinic visits. Separate Cox models evaluated the relationship between retention measures and all-cause mortality with follow-up time starting at 24 mos. Next, separate Cox models evaluated the association between missed visits and all-cause mortality among the subset of patients classified as retained according to the IOM and DHHS core indicators, respectively, and 32% had zero missed visits over 24-mos following ART start. Subsequently, 333 patients (8.5%) died during 17841 person-years follow-up. In separate multivariable Cox models, failure to achieve the IOM indicator (HR=2.2; 95%CI=1.8-2.8), the DHHS indicator (2.4; 1.9-3.0), and missed clinic visits at 24-mos (1-2 no shows: 2.0; 1.5-2.8, >2 no shows: 3.2; 2.4-4.5) were all associated with increased long-term mortality. Roughly two-thirds of patients classified as retained by the IOM and DHHS core indicators had one or more no show clinic visits in the 24-mos following ART start. Separate multivariable Cox models restricted to patients classified as retained by the IOM and DHHS core indicators demonstrated increased mortality risk among patients with more missed clinic visits (IOM: 1-2 no shows 1.8; 1.2-2.7, >2 no shows: 3.7; 2.4-5.6 and DHHS: 1-2 no shows 1.7, 1.1-2.6, >2 no shows: 3.7; 2.3-5.6).

Conclusion: We found that a combination of 3 variables available in standard HIV surveillance predicted the likelihood that a PLWHA was residing locally and contactable. Although the accuracy of this score requires external validation, choosing not to investigate cases with “In Area, Contactable” scores of <3 would allow health departments to avoid approximately one-third of all investigations while missing only 5% of contactable persons.

983
Conclusions: These data are among the first to provide empirical validation of the IOM and DHHS core indicators of retention in care with clinical outcomes. Both measures were strongly associated with long-term mortality among ART initiators. However, study findings suggest assessment of missed clinic visits, in conjunction with these core indicators, can meaningfully enhance prognostic value for all-cause mortality, with implications for health care policy and clinical care.

984 National ART Monitoring System Enables Robust Transfer-Adjusted Retention Analyses in Namibia

Anna Jonas1, Andrew Maher2, Roy W. Shiraishi3, Michael de Klerk4, Francina Kaindie-Tjituka5, Gram Mutandi6, Sadhna V. Patel7, Anne-Marie Nitschke8, Alexina Muadinohamba1, David W. Lowrance2

1Directorate of Special Programmes, Ministry of Health and Social Services, Windhoek, Namibia, 2Division of Global HIV/AIDS, US Centers for Disease Control and Prevention, Windhoek, Namibia, 3Division of Global HIV/AIDS, US Centers for Disease Control and Prevention, Atlanta, GA, United States

Background: Migration of persons living with HIV is associated with loss to follow-up (LTF) and poses a challenge to monitoring and evaluation of ART programs. Aims: To describe migration patterns in Namibia and assess the impact of migration on ART program outcomes.

Methods: We evaluated all HIV-infected adults initiating ART in all 213 public health facilities in Namibia from January 2003 to December 2013. We used Kaplan-Meier analysis to estimate trends in retention, unadjusted and adjusted for IFT through de-duplication of TP from the cumulative cohort. Retention was defined as visiting a health facility within 90 days of the next scheduled follow-up visit.

Results: Before adjusting for IFT, 167,484 adult patients initiated ART from 2003 to 2012. After adjusting for IFT, only 140,224 patients initiated ART; of these, 59.6% were female and median age at initiation was 35 years (IQR: 30 to 42). Unadjusted and adjusted retention proportions at 12, 24, 36, and 48 months were: 0.88/0.86, 0.85/0.83, 0.83/0.81 and 0.81/0.79 in the 2004 initiation cohort; 0.93/0.91, 0.89/0.88, 0.85/0.84 and 0.81/0.81 in 2006; 0.89/0.88, 0.83/0.84, 0.77/0.80 and 0.70/0.75 in 2008; 0.87/0.88, 0.77/0.81, 0.68/0.73 and not available (NA) in 2010 and; 0.81/0.82, NA, NA and NA in 2012. 10,725 (25%) of 43,028 patients classified as lost in the unadjusted analysis were identified as being retained at a different facility after adjustment for IFT.

Conclusions: Evaluation of ART patient outcomes in resource-limited settings is essential to understanding program quality and impact. Heterogeneous data systems may have led to underestimation of retention and other longitudinal outcomes. Consistent with previous reports from other countries this unadjusted analysis shows trends of declining retention, corresponding to service scale-up and decentralization. However, ART retention in cohorts improved after adjustment for IFT. This analytic approach allows for robust determination of ART program outputs by de-duplicating TP from cumulative cohort analyses. National standardized ART monitoring systems like Namibia’s may be a best practice for other countries as routine tracking and quantification of TP enables more robust retention analysis and program monitoring.

985 Migration After HIV Diagnosis, United States

Lorena Espinoza, H. Irene Hall, Aruna Surendera Babu, Tian Tang, Mi Chen

Division of HIV/AIDS Prevention, CDC, Atlanta, GA, United States

Background: Early diagnosis, prompt linkage to care, and retention in ongoing care benefit the health of people living with HIV and can reduce the onward transmission of HIV. However, continuing care may be affected by people relocating to seek better social or medical support, and local jurisdictions need accurate information on patient populations for care planning and public health intervention. Very few studies have reported on U.S. migration among persons diagnosed with HIV.

Methodology: Using data from the National HIV Surveillance System (NHSS) reported through March 2013, we assessed migration to another state among persons diagnosed with HIV in the United States through 2009. Persons living with HIV infection may move from state to state; therefore, may be reported to CDC from more than one state. CDC provides information on potential duplicate reporting to state health departments based on information CDC receives, and state health departments collaborate to determine whether these potential duplicate reports are the same person or not. Using information from the de-duplication process, CDC determines inter-state migration. Migration was assessed from HIV diagnosis through 2010 overall (ever) and within 12 months after HIV diagnosis. We defined area of residence as urban (metropolitan area ≥500,000 population), suburban (metropolitan area of 50,000-499,999 population), or rural (nonmetropolitan population). We calculated prevalence ratios (PR) and 95% confidence intervals (CI) to determine factors associated with migration.

Results: Of 1,503,778 persons diagnosed with HIV in the United States through 2009, 9.9% ever migrated to another state and 2.5% migrated within 12 months of diagnosis. A higher percentage of females ever migrated compared with males (PR =1.30, 95% CI 1.28, 1.31). Compared with whites, fewer blacks ever migrated (PR=0.94, 95% CI 0.92, 0.95) while more Hispanics migrated (PR=2.38, 95% CI 2.34, 2.43). Compared to persons living in the Northeast at time of HIV diagnosis, a higher percentage of persons living in the South migrated (PR=6.95, 95% CI 6.32, 7.64).

Persons in suburban (PR=1.35, 95% CI 1.33, 1.37) and rural (PR=1.32, 95% CI 1.29, 1.34) areas of residence migrated more than persons in urban areas. Results were similar for persons who migrated within 12 months of HIV diagnosis.

Conclusions: Higher geographic mobility among persons after a diagnosis with HIV was observed among women, Hispanics and persons living in the South. Local jurisdictions should consider the impact of migration while planning prevention, linkage to care, and retention in care programs. HIV interventions can be tailored to the characteristics and needs of these populations.
**Early Linkage To HIV Care and Antiretroviral Therapy Use Among MSM — 20 US Cities, 2008 and 2011**

Brooke Hoots, Teresa Finlayson, Cyprian Wejnert, Gabriela Paz-Bailey for the NHBS Study Group  
CDC, Atlanta, GA, United States

**Background:** Over half of HIV infections in the United States occur among men who have sex with men (MSM). Antiretroviral therapy (ART) is now recommended for all infected persons to improve health and prevent HIV transmission. Timely linkage to care is a key step for initiation of ART. We analyzed data from MSM in the National HIV Behavioral Surveillance system (NHBS) to determine the prevalence of early linkage to care and ART use by key characteristics and evaluate changes in prevalence from 2008 to 2011.

**Methodology:** Venue-based, time-space sampling was used to recruit men for interviews and HIV testing in 20 cities participating in NHBS in 2008 and 2011. Early linkage to care was defined as a self-reported clinic visit for HIV care within 3 months of diagnosis and current ART use was defined as use at the time of interview. Self-reported HIV-positive MSM who had ≥ 1 partner in the past 12 months were included in the analyses. Early linkage models were further restricted to those diagnosed with HIV ≥ 3 months prior to interview. We used linear mixed models clustered on city to examine differences in the two outcomes between 2008 and 2011. To explore whether temporal changes in the outcomes varied by demographics, interaction terms were included in the models.

**Results:** Prevalence of early linkage to care was 75% (599/802) in 2008 and 79% (757/964) in 2011 (P = .09). In both years, early linkage was highest among those with higher education and income, gay-identified vs. bisexual- or heterosexual-identified, and at older age at diagnosis (≥ 30). In a multivariable model adjusted for race/ethnicity, age at diagnosis, and region, prevalence of early linkage did not change significantly between years overall (P = .17) and only changed significantly for Hispanic ethnicity (75% in 2008 vs. 84% in 2011, P = .04). Prevalence of ART use was 66% (567/854) in 2008 and 77% (791/1,030) in 2011 (P = .0001). Higher ART use was observed among whites, older age groups, men with higher education and income, and gay-identified MSM in both years. In a multivariable model adjusted for race/ethnicity, current age, income, sexual identity, and region, ART use significantly increased from 2008 to 2011 (P = .02). ART use also increased significantly among most races/ethnicities, younger age groups (< 30), men with higher income, bisexual- or heterosexual-identified MSM, and men interviewed in Western cities.

**Conclusions:** While the prevalence of early linkage among MSM did not increase significantly between 2008 and 2011, the prevalence of ART use increased among most demographic groups. These findings demonstrate that progress is being made in getting people on HIV treatment, but that more efforts are needed to link patients to clinical care within 3 months of diagnosis and improve coverage of ART.

**The Impact of Opioid Substitution Treatment On Highly Active Antiretroviral Treatment Adherence**

Bohdan Nosyk, Jeong Min, Viviane Lima, Guillaume Colley, Benita Yip, Evan Wood, Julio Montaner  
BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada

**Background:** Opioid substitution treatment (OST) has been associated with enhanced uptake and adherence to highly active antiretroviral therapy (HAART), however standard methods for estimating the causal effect of a time-varying treatment on the mean of a repeated measures outcome may be biased when there are time-dependent variables that are simultaneously confounders of the effect of interest and are predicted by previous treatment. In our context, previous HAART adherence is hypothesized to be a time-dependent confounder for the effect of OST on future HAART adherence. Our objective was to determine the impact of OST exposure on adherence to HAART among HIV-positive opioid dependent individuals.

**Methodology:** We selected all HAART-eligible HIV-positive individuals ever accessing opioid substitution treatment between January 1st, 1996 and March 31st 2010 within a linked population-level database for British Columbia, Canada, after meeting the criteria for HAART initiation. A marginal structural model was estimated using monthly-updated inverse probability of treatment weights (IPTW). The primary outcome measure was 95% HAART adherence, according to pharmacy refill compliance records. Exposure to OST was defined as at least 21 days of OST receipt in a calendar month. We controlled for fixed and time-varying covariates, including age, gender, ethnicity, health authority of residence, calendar year, OST history at HAART eligibility, AIDS status, CD4 and prior HAART exposure in estimated IPTW.

**Results:** Among 12,349 HIV-positive individuals observed in BC between 1996 and 2010, 1,811 (14.7%) accessed OST, and 1,347 (10.9%) were selected for the study. Subjects were 39% female, were of median age 35 (interquartile range: 29-41) at HAART eligibility, and had a median of 6.6 years (2.8-10.9) of follow-up. During OST, individuals spent a median 55% (20%-85%) of the time on HAART, while out of OST individuals spent only 26% (7%-58%) of the time on HAART. The unadjusted odds of HAART adherence during OST exposure was 2.26 (95% confidence interval: 2.01-2.54), while the adjusted odds, estimated within the marginal structural model, was 2.17 (1.90, 2.49).

**Conclusions:** Our results demonstrate that access to OST more than doubles the odds of HAART adherence among opioid-dependent individuals with HIV. This study informs funding decisions for OST and strategies to increase access to HAART.

**Correlation Between Community Variables and HIV Linkage To Care and Viral Suppression, Atlanta, GA**

Neeta D. Goswami, Sharoda Dasgupta, Patrick Sullivan, Deepali Rane, Carlos del Rio, Travis Sanchez  
1Medicine, Emory University School of Medicine, Atlanta, GA, United States, 2Emory University Rollins School of Public Health, Atlanta, GA, United States, 3Georgia Department of Public Health, Atlanta, GA, United States

**Background:** Linkage and retention in care are central to reducing morbidity and mortality for HIV-infected persons. The Centers for Disease Control and Prevention recommends linkage to care within three months of diagnosis, but 33% fail to link within this period. An HIV-infected person’s residence may be critical to his potential for linkage and retention in care after diagnosis. We hypothesize that within metro Atlanta, low “community linkage to care” and “community viral suppression” may correlate with neighborhood-level variables at the zip code level, including high levels of poverty and income inequality, low educational attainment, high proportion vacant houses, and poor public transportation access.
**Methodology:** We used data from the Georgia Department of Public Health, U.S. Census Bureau American Community Survey, and the Atlanta Regional Commission to examine distributions of neighborhood-level variables and statistical correlations with community linkage to care (average percent linked to care within three months) and community viral suppression (average percent with reported viral load below 200 cells/mL), by zip code tabulation areas (ZCTAs). The analysis included persons living in six Georgia counties comprising the metro Atlanta area with a new HIV diagnosis reported through Georgia’s Electronic HIV/AIDS Reporting System from January 1, 2006 through December 31, 2010. With zip codes as observations, we evaluated correlations between neighborhood-level variables and two primary HIV outcomes, community linkage to care and community viral suppression. Pearson’s and Spearman’s correlations were used to evaluate associations between zip code level variables and primary outcomes.

**Results:** In the 123 included ZCTAs, median HIV incidence was 203 per 100,000 persons. Overall, 53% of people diagnosed with HIV linked to care within three months of diagnosis and 45% achieved viral suppression. 16% of the population was living below the poverty line, and 88% had at least a high school diploma equivalent. Income inequality was not prominent (mean Gini coefficient 0.44). On average, 3% of occupied houses lacked telephone service, and 13% of houses were vacant. There was a median of 54 public bus stops in each zip code. Areas of high poverty and greater number of bus stops correlated with poor linkage to care and lower levels of viral suppression. Higher educational attainment and low proportion vacant houses correlated with greater community virologic suppression.

**Conclusions:** Certain neighborhood-level variables may correlate with community-level linkage to care and viral suppression for HIV-infected persons. Bus stop density may be a marker of high poverty, in addition to an indicator of transportation access, in the linkage and retention in care paradigm.

**Tuesday March 4, 2014, 2:30 pm – 4:00 pm**  **Exhibit Hall D**
**Cascade of Care, Community Viral Load, and Viral Suppression**

### 989 Viral Suppression Among Foreign-Born HIV-Infected Persons in the United States

**Tanya R. Myers** 1,4, *Jaciek Skarbinski* 1
1CDC, Atlanta, GA, United States, 2LSHTM, London, United Kingdom

**Background:** Few national-level data exist on the characteristics of and clinical outcomes among foreign-born HIV-infected persons. Using data from the Medical Monitoring Project (MMP), a nationally representative survey of HIV-infected adults receiving medical care in the United States, we report on the characteristics of and clinical outcomes among foreign-born HIV-infected adults.

**Methodology:** We used data from the 2009 MMP cycle collected from 461 outpatient HIV care facilities in 16 states and Puerto Rico on 4217 adult participants. Participants were classified as foreign-born if they listed a country or territory of birth other than the United States or Puerto Rico during interview. Receipt of antiretroviral therapy (ART) was defined as documented ART prescription in the medical record in the past 12 months. Viral suppression was defined as documented most recent viral load measurement of ≤200 copies/mL in the medical record. We used multivariable logistic regression to assess the independent association between foreign-born status and ART prescription and viral suppression after adjusting for confounding. All analyses account for clustering, unequal selection probabilities and non-response.

**Results:** In all, 529 participants (13.1%) self-identified as foreign-born; the majority (61.2%) was from either Central America or the Caribbean. Over 90% of foreign-born persons were diagnosed with HIV after entry into the United States. Foreign-born persons were more likely to be young, male, Hispanic, living at or below the poverty level, and uninsured compared to native-born persons. Adjusting for potential confounders including age and language, there was no association between foreign-born status and ART prescription (adjusted odds ratio aOR 0.81; p 0.30) or viral suppression (aOR 1.10; p 0.55). However, in multivariable modeling assessing foreign-born status and region of birth, foreign-born persons from the Caribbean were less likely to be prescribed ART (aOR 0.43; p 0.005) and to achieve viral suppression (aOR 0.51; p 0.011) than native-born persons.

**Conclusions:** In this nationally representative sample of HIV-infected persons receiving medical care, foreign-born persons overall were equally likely to be prescribed ART and achieve viral suppression compared to native-born persons. However, significant disparities among foreign-born persons exist, with persons from the Caribbean being less likely to be prescribed ART and achieve viral suppression. Efforts to improve clinical outcomes among HIV-infected foreign-born persons should be strengthened, especially for migrants from the Caribbean.

### 990 Mapping Community Viral Load and Transmission Potential Prevalence of HIV Among MSM in New York City

1Laboratory of Infectious Disease Prevention, New York Blood Center, New York, NY, United States, 2Division of Infectious Diseases, Columbia University Medical Center, New York, NY, United States, 3University of Pittsburgh, Pittsburgh, PA, United States, 4Laboratory of Social and Behavioral Sciences, New York Blood Center, New York, NY, United States, 5Rutgers University, Rutgers, NJ, United States, 6Department of Epidemiology, Columbia University Mailman School of Public Health, New York, NY, United States, 7New York University, New York, NY, United States

**Background:** Community viral load (CVL) and transmission potential (TPP) are aggregate biological markers used to monitor population-level HIV transmission. Lower CVL and TPP have been shown to be associated with decreased HIV incidence or new diagnosis. Previous studies of CVL and TPP have been based on place of residence. Data on CVL and TPP based on where MSM have sex can provide a more nuanced assessment of potential transmission.

**Methodology:** The NYC M2M study recruited MSM in NYC via modified time-space, venue-based sampling and web-based recruitment from 2010-12. Participants identified the neighborhood where they most frequently had sex in the last 3 mos. using Google Earth, and completed an ACASI questionnaire and a sexual network inventory. They received HIV testing and, if HIV+, CD4 and viral load (VL) testing. For geographic analysis, CVL was calculated as median VL of HIV+ men. TPP was defined as the percent of the sample with VL>20 copies/mL. ArcGIS was used to visualize median CVL and TPP by
community districts of most frequent sex among HIV+ men. For comparisons by sociodemographics and risk behaviors, median VL and TPP were used and compared using Kruskal-Wallis and chi-square tests.

Results: Of total 1,458 men, 327 (22%) reported being HIV+; 195 HIV+ men (60%) agreed to CD4 and VL testing. 84 men (43%) had undetectable VL; median CVL was 2,201 copies/mL among those with detectable VL. Overall median CD4 was 545 cells/mL. Maps of CVL and TPP by geographic areas of most frequent sex are shown. Median VL and TPP were significantly higher for men who were Black or Hispanic, newly HIV diagnosed, had no prior HIV treatment, last engaged in medical care >6 mos. ago, and had low HIV treatment adherence self-perception. Higher median VL was also associated with recent drug use; higher TPP was also associated with age <30 years, lower education level, and no unprotected anal sex (UAS) in last 3 mos.

Conclusions: The distribution of TPP by most frequent sex geographic areas provided a slightly different picture of potential HIV transmission than CVL among MSM in NYC. Both VL and TPP were higher among Blacks and Hispanics, newly HIV diagnosed, and those infrequently engaged in medical care. The finding of no recent UAS among those with higher TPP is encouraging.

991  HIV Care and Viral Suppression Among Persons Living With HIV/AIDS, New York City 2006-2010

Lucia V. Torian, Qiang Xia, Ellen W. Wiewel
HIV Epidemiology Program, New York City Department of Health, Long Island City, NY, United States

Background: New York City (NYC) has measured its baseline and will monitor its progress toward meeting the care and viral suppression goals of the National HIV/AIDS Strategy.

Methodology: Using the city’s population-based HIV/AIDS surveillance registry we measured trends in retention in care (≥1 visit/year), engagement in care (≥2 visits/year, 3 months apart), and viral suppression (<400 copies/mL) in persons diagnosed and presumed to be living with HIV/AIDS (PLWHA) in NYC during 2006-2010. We compared results obtained with the crude denominator most frequently used for national estimates (persons diagnosed and reported in NYC and not known to be dead) against a denominator that was adjusted to reflect a more accurate count of PLWHA in the city during the
analysis period. We did this by removing all those with no HIV-related laboratory tests (WB, CD4, viral load of genotype) reported in NYC in the five years preceding the year of analysis on the premise that previously diagnosed persons for whom no data existed for such a long period of time, the majority of whom would have needed care due to advancing disease, were not likely to be living in NYC. The adjusted PLWHA population (N=84,146) for 2010 was used to describe the outcome measures by demographic characteristics, transmission risk and clinical status, and to estimate adjusted prevalence ratios (PRs) and 95% confidence intervals (CIs).

Results: The percentage of persons retained and engaged in care was stable in both populations. In the crude population, retention was 64.7% in 2006 and 64.1% in 2010; engagement was 52.9% in 2006 and 53.7% in 2010. Using the adjusted population, retention was 82.5% in 2006 and 81.8% in 2010; engagement was 67.5% in 2006 and 68.5% in 2010. In contrast, viral suppression increased from 34.7% in 2006 to 46.4% in 2010 in the crude population and 44.3% to 59.1% in the adjusted population. Blacks were least likely to have a suppressed viral load (PR=0.89, 95% CI: 0.87, 0.90), and PLWHA at both ends of life (age <13 and age ≥50) did better at viral suppression than those in the middle age brackets (PR=1.58 [95% CI: 1.43, 1.76] and PR=1.61 (PR 1.56, 1.65), respectively).

Conclusions: NYC experienced stable rates of retention and engagement in care but significant increases in viral suppression during 2006-2010. Higher proportions retained, engaged and virally suppressed than published national estimates may reflect a combination of the more accurate case counting that is available at the local level, comprehensive reporting of HIV-related laboratory test results, the widely accessible, affordable HIV care that is available in NYC, and early adoption of early ART by local clinicians.

992LB Low Incidence and High Population Viral Suppression in Malawi: The Chiradzulu HIV Incidence Study

David Maman1, Sophie Masson2, Benson Chilema2, Charles Masiku3, Elizabeth Szumlin4, Ahidjo Ayoubi5, Benjamin Riche6, Etard Jean-Francois1-7, Amanda D. Castel8, Alan E. Greenberg, Heather Young, Mariah M. Kalmin, DC Cohort Executive Committee

Background: The rural district of Chiradzulu, in Malawi, was the site of the first antiretroviral (ART) program implemented in sub-Saharan Africa by Médecins Sans Frontières (MSF) together with the Ministry of Health. ART became available there in early 2001, decentralization of care was completed in 2003, and task shifting allowing nurses to initiate ART started in 2006. By the end of June 2013, 27,000 patients (within a district of 280,000 inhabitants in total) were receiving ART. Here we present findings of the Chiradzulu HIV Impact in Population Study (CHIPS), which directly measured HIV incidence, population viral load and coverage at each step within the cascade of care in early 2013, after 15 years of a district-wide program. This is one of the first population-level studies incorporating these specific metrics, which WHO recently identified as the most relevant for evaluating and optimizing both the therapeutic benefit of HIV treatment to individuals and the public health effectiveness of “treatment as prevention” strategies.

Methodology: Cross-sectional population-based survey. The study was conducted between February and May 2013. Using a multistage cluster sampling method, we recruited all individuals age 15 to 59 living in 4,125 selected households. Each individual who agreed to participate was interviewed and tested for HIV at home. All participants who tested positive also had their CD4 count and viral load measured. The Lag and Biorad Avidity assays were used to distinguish recent from long-term infection.

Results: Of 8,271 individuals eligible for the study, 7,269 agreed to participate and were tested for HIV (94.1% inclusion for women and 80.3% for men). Overall HIV prevalence was 17.0% (95%CI 16.1 - 17.8). Based on the LAg and Biorad avidity assays results, overall incidence was 0.39 (95%CI 0.0-0.77) and 0.34 (95%CI 0-0.72) new cases per 100 Person-Years respectively. Incidence was higher among women compared to men (0.57 vs 0.18 new cases per 100PY).

Coverage at steps along the HIV care cascade was found to be as follows. Among the total HIV-infected population, 76.7% (95%CI 74.4 - 79.1) had been previously diagnosed, 71.2% (95%CI 68.6-73.6) were in care, 65.8% (95%CI 62.8-68.2) were on ART and 61.8% (95%CI 59.0-64.5) had a viral load below 1,000 copies. Proportion of population viral suppression (VL<1,000copies/ml) was higher in women compare with men (65.3% vs 53.9%, p<0.001).

Conclusions: This population incidence study suggests that high levels of population viral suppression and low incidence can be achieved in high-prevalence settings in sub-Saharan Africa. However, no causal relation between popluation viral suppression and low incidence can be made from this cross-sectional study.

993 Disparities in Viral Suppression Among a Large Cohort of HIV-Infected Persons in Washington, DC

Amanda D. Castel, Alan E. Greenberg, Heather Young, Mariah M. Kalmin, DC Cohort Executive Committee

Dept. of Epidemiology and Biostatistics, The George Washington University, Washington, DC, United States

Background: Although achieving viral suppression (VS) is the ultimate goal of the HIV care continuum, it is well known that disparities exist among particular subpopulations with regard to treatment access. Accordingly, one of the goals of the National HIV AIDS Strategy is to reduce HIV-related health disparities. We sought to identify potential disparities in VS among an urban cohort of HIV-infected persons in care.

Methodology: Data from the DC Cohort, a longitudinal observational cohort study of HIV-infected persons in care in Washington, DC were used for this analysis. Data were abstracted from participants’ electronic medical record data and through manual data abstraction from 13 participating clinical sites. VS was defined as a viral load (VL) <200 copies/ml at the time of enrollment or at the most recent VL measurement. Descriptive statistics, bi- and multivariate logistic regression analyses were performed to identify factors associated with achieving VS.
Results: Among the first 3,589 participants, most were black (75%), male (75%), were a median age of 47 years at enrollment, and 40% were infected through male-to-male sexual contact. At enrollment, 3,303 (92%) participants were prescribed antiretrovirals with a mean treatment duration of 5.1 years, and 74.2% were virally suppressed (VS). Unadjusted logistic regression analysis found that those not VS were significantly more likely to be black, female, younger, have temporary housing, public insurance, unemployed, have co-morbid alcohol or substance abuse conditions and be treatment experienced. After multivariable adjustment including for HAART therapy, blacks (aOR:0.48; 95%CI:0.30, 0.78); younger participants (aOR:1.18; 95%CI:1.10, 1.26 per 5 year increase); and treatment inexperienced participants remained significantly less likely to be VS. Viral suppression was not significantly associated with insurance status, employment, duration of HIV infection or co-morbid medical conditions including hepatitis B, C, depression, or diabetes. Among participants who were not VS, 16.9% had VL ≥100,000 copies/ml at enrollment. Longitudinal analysis among 361 participants from consent date forward found that after 373 person-years of follow-up, 88.6% of participants remained VS; the median VL among unsuppressed participants was 1,430 copies/ml.

Conclusions: Among a large urban cohort of HIV-infected persons, the majority of persons were able to achieve and maintain viral suppression; however, disparities in viral suppression exist with regard to race, sex, social and economic factors. Efforts to identify these populations with disparate outcomes will allow for appropriate targeting of resources to improve viral suppression and achieve national goals.

994 Community Viral Load and HIV Incidence: A Multi-City Study of High-Risk Populations in India
Sunil S. Solomon1,2, Shruti H. Mehta3, Aylur K. Srikrishnan3, Oliver Laeyendecker1,4, Shanmugam Saravanani2, Allison McFall2, Pachamuthu Balakrishnan2, Suniti Solomon4, David D. Celentano1, Gregory M. Lucas1
1Johns Hopkins University, Baltimore, MD, United States, 2YR Gaitonde Centre for AIDS Research and Education, Chennai, India, 3National Institute of Allergy and Infectious Diseases, Bethesda, MD, United States

Background: Community viral load (CVL) has been proposed as a barometer of HIV transmission risk within populations. However, there are different ways in which CVL may be measured and few data are available comparing methods with HIV incidence in representative samples from high-risk populations.

Methodology: We recruited men who have sex with men (MSM) from 12 cities and injection drug users (IDU) from 10 cities across India (only 1 city overlapped) for HIV counseling and testing (target recruitment of 1,000 per site) using respondent-driven sampling, a method that produces unbiased estimates in ‘hidden’ populations. We constructed 4 measures of CVL: 1) average log10 HIV RNA in those aware of their HIV-positive status (CVL-aware), 2) average log10 HIV RNA in all HIV-infected (CVL-positive), 3) HIV prevalence, and 4) prevalence of infected individuals with HIV RNA >1,000 c/ml (viremia prevalence). CVL-aware reflects HIV RNA among people accessing care, but does not consider the contribution of undiagnosed individuals. CVL-positive includes data from both diagnosed and undiagnosed individuals. Viremia prevalence reflects both the HIV prevalence and the proportion with non-suppressed HIV RNA in a community. We estimated HIV incidence in each community with a validated multi-assay algorithm that used HIV RNA, CD4, BED, and avidity in HIV seropositive participants. We used Spearman correlation coefficients and Poisson regression to assess the associations between site-level HIV incidence estimates and the 4 CVL measures. HIV prevalence and viremia prevalence were loge-transformed, and all CVL indices were expressed per standard deviation (SD) to facilitate comparisons.

Results: A total of 21,495 participants were recruited across 22 sites (12,022 MSM and 9,473 IDU). The median (range) site-level CVL measures were 3.0 log10 c/mL (2.5, 4.2) for CVL-aware, 3.8 log10 c/mL (2.6, 4.4) for CVL-positive, 10.7% (1.9, 47.2) for HIV prevalence, and 5.3% (1.6, 26.4) for viremia prevalence. The median (range) site-level HIV-incidence was 0.5% per year (0, 3.4). The Table shows correlations (r) and incidence rate ratios per SD increase in each of the 4 CVL indices, the latter adjusted for MSM vs. IDU site. Patterns were similar in the MSM and IDU strata.

| Associations between CVL indices and HIV incidence among MSM and IDU in 22 Indian cities |
|---------------------------------------------|-----------------|--------------------------|
| Community viral load index                 | Rho (P value)   | Incidence rate ratio (95% confidence interval) |
| CVL-aware                                   | 0.36 (0.11)     | 1.54 (1.17, 2.03)        |
| CVL-positive                                | 0.19 (0.40)     | 1.59 (1.17, 2.16)        |
| HIV prevalence                              | 0.56 (0.007)    | 1.61 (1.04, 2.55)        |
| Viremia prevalence                          | 0.72 (<0.001)   | 2.05 (1.35, 3.12)        |

Conclusions: Among the CVL indices evaluated, the prevalence of viremic individuals was the most strongly associated with current HIV incidence in a multicity study of MSM and IDU in India.

995 Declines in Community Viral Load in the Context of Population Prevention Strategies in the Bronx
David B. Hanna1,3, Uriel R. Felsen1,3, Minny S. Ginsberg1, Barry S. Zingman1,3, Robert S. Beil1,2, Donna C. Futterman1,3, Howard D. Strickler1, Kathryn Anastos1,2
1Albert Einstein College of Medicine, Bronx, NY, United States, 2Montefiore Medical Center, Bronx, NY, United States

Background: Multiple HIV prevention strategies involving expanded HIV testing and implementation of expanded treatment guidelines, both population-wide and institutionally, have been recently instituted in the catchment area of the Montefiore Medical Center clinical network (MMC), the largest provider of HIV care in the Bronx, New York. We aimed to examine the association between the introduction of these initiatives and improvements in community viral load between 2007 and 2012.
**Methodology:** We used data from the Einstein-Montefiore Center for AIDS Research (CFAR) HIV Integrated Clinical Database, which combines electronic medical records, laboratory test results, prescription data, and clinical intake information. Inclusion criteria included HIV infection, intake at an outpatient clinic affiliated with MMC, age 13+, and at least one HIV-1 viral load (VL) measure obtained during the study period. We described community viral load based on the geometric mean of the last recorded VL per individual in each year, including both those in regular care and those in sporadic care. We examined calendar-year trends in VL suppression (<200 copies/mL) in the population overall and among prespecified subgroups. We assessed disparities in VL suppression by age, sex, race/ethnicity, and transmission risk using Poisson regression with generalized estimating equations.

**Results:** We analyzed 6,998 HIV-infected individuals receiving outpatient care at MMC between 2007 and 2012 (median age 48, interquartile range 41-55, 47% Hispanic, 45% black). The median HIV-1 VL throughout this period was <200 copies/mL. We identified a significant decrease in the geometric mean VL, from 567 copies/mL in 2007 to 90 copies/mL in 2012, and a corresponding increase in the percent of individuals with a suppressed VL, from 57% to 75% (both p<0.0001). Population groups significantly less likely to have a suppressed VL were younger individuals, those of black race or Hispanic ethnicity, men who have sex with men [92% of whom were black or Hispanic], and perinatally-infected individuals. In adjusted analyses, only age and race/ethnicity remained as significant barriers to suppression. Increases in VL suppression occurred across most subgroups, including those traditionally believed to be less engaged in care such as injection drug users, but were less consistent among those age 13-24 (pinteraction=0.05).

**Conclusions:** In this high HIV prevalence area, population-wide HIV prevention strategies, including implementation of expanded treatment guidelines, coincided with improvement in community viral load among most groups. More attention is needed to address continued disparities in the care continuum in the Bronx, particularly among young people.

### Cascade of Care

**996** New Epidemiological Indicator To Estimate the Gap Between WHO Eligibility ART Criteria and Reality

Jacques D. A. Ndawinz1, Xavier Anglaret2,3, Eric Delaporte2,3,4, Sinata Koulla-Shiro5, Delphine Gabillard1,6, Dominique Costagliola2,6, Virginie Supervie2,3

1Sohnls, Paris, France; 2Centre 897, INSERM, Bordeaux, France; 3Isped, University of Bordeaux, Bordeaux, France; 4UMR 145, University of Montpellier 01, Montpellier, France; 5IRD, Montpellier, France; 6Central Hospital, Yaoundé, Cameroon; 7UMR 5943, UPMC Paris Univ 06, Paris, France; 8UMR3, INSERM, Paris, France

**Background:** Many HIV-infected individuals initiate antiretroviral therapy (ART) late. CD4 count distribution at ART initiation is used to assess the timeliness of ART. We propose a new additional indicator to estimate the gap between the WHO recommended and the actual timing of ART initiation: the lost time in starting ART (LTISA). Here, we estimated LTISA in Cameroon over time.

**Methodology:** LTISA was calculated by subtracting the mean time from HIV seroconversion to ART eligibility threshold to the mean time from HIV seroconversion to ART initiation. We estimated the time from seroconversion to CD4 cell count thresholds <350 and <200 cells/mm3 using data from the ANRS 1220 Primo-CI cohort of HIV seroconverters. CD4 cell count declines were analyzed by fitting a mixed linear model. From this model, we derived an equation for the time it takes for an HIV-infected person to reach a given CD4 threshold, which depended on the estimated CD4 count at seroconversion and CD4 cell count slope. To estimate the time from seroconversion to ART initiation in Cameroon we conducted a survey in a nationally representative sample of HIV facilities. Medical records of adult HIV patients who initiated ART in these facilities in the month of October over the period 2007-10 were reviewed to collect sociodemographic and CD4 cell counts at ART initiation data. We then assessed how many CD4 counts were lost from seroconversion to ART initiation, and convert these losses into time using the aforementioned equation.

**Results:** 3037 CD4 count measurements from 350 seroconverters of the Primo-CI cohort were used in the mixed model. Mean CD4 cell counts at seroconversion was 550/mm3 (95% confidence intervals (CI): 526-574) and mean CD4 cell counts decline during the first year after seroconversion was 47 cells/mm3 (95% CI: 46-48). We estimated that median times from seroconversion to CD4 cell counts <350 and <200 cell/mm3 were, respectively, 4.4 years (inter-quartile range (IQR): 2.0-7.6) and 8.1 years (IQR: 5.2-11.3). Median CD4 cell counts at ART initiation among 4154 Cameroones patients was 144/mm3 (IQR: 67-223). We found that median times from seroconversion to ART initiation ranged from 9.1 to 11.0 years, depending significantly on gender, age and period of ART initiation. Median time from seroconversion to ART initiation was shorter after than before the adoption of 2010 WHO eligibility ART criteria (9.3 versus 10.2 years). Despite this decrease, LTISA in Cameroon increased from 2.9 to 5.4 years over the same period because the CD4 threshold for ART eligibility was increased from 200 to 350 cells/mm3.

**Conclusions:** LTISA could provide useful information to monitor progress made by countries in reducing gaps between the WHO eligibility ART criteria and the actual timing of ART initiation.

Nikoloz Chkhartishvili1, Otar Chokoshvili2, Lali Sharanadze3, Jack A. DeHovitz4, Carlos del Rio5, Tengiz Taertsadze5

1Infectious Diseases, AIDS and Clinical Immunology Research Center, Tbilisi, Georgia; 2Faculty of Medicine, Tbilisi State University, Tbilisi, Georgia; 3State University of New York Downstate Medical Center, Brooklyn, NY, United States; 4Emory University, Atlanta, GA, United States; 5Tbilisi State University, Tbilisi, Georgia

**Background:** The HIV epidemic is rapidly evolving in the Eastern Europe. There is limited information about the patterns of engagement in HIV care in this region. We aimed to assess trends in cascade of care in the country of Georgia over the period of 2008-2012.

**Methodology:** The analysis included all adult (age ≥18 years) HIV patients diagnosed in Georgia from 1989 through 2012. Data was extracted from the national HIV/AIDS database. The proportions of patients linked to care, retained in care, receiving antiretroviral therapy (ART) and with viral load <400 copies/ml were calculated from the total number of diagnosed HIV patients known to be alive at the end of each calendar year.
Results: A total of 3,554 adult persons were diagnosed with HIV in Georgia and 779 of them died by the end of 2012. Among diagnosed patients 74% were men and 55% had history of injection drug use (IDU). Linkage to care increased from 73% to 84% (p<0.0001), with the most notable improvement seen among persons with history of IDU (68% vs. 80%, p<0.0001). The proportion of patients retained in care increased from 59% to 71% (p<0.0001). However, retention among those linked to care did not vary significantly over the study period. Phased implementation of ART initiation criteria of CD4 count <350 cells/mm3 led to marked increase in ART coverage and proportion of virally suppressed patients. Average CD4 cell count at ART initiation increased from 133 cells/mm3 to 194 cells/mm3 (p<0.0001). Compared to non-IDUs, persons with history of IDU were less likely to engage in various stages of care at any studied year.

Conclusions: Our analysis demonstrates that engagement in the continuum of HIV care in Georgia has been improving over time. IDUs are at higher risk of suboptimal engagement. Additional efforts are needed to increase retention in care and earlier initiation of ART.

998 Use of National Standards To Monitor HIV Care and Treatment in a High Prevalence City – Washington, DC
Amanda D. Castel, Alan E. Greenberg, Mariah M. Kalmin, Heather Young, DC Cohort Executive Committee
Dept. of Epidemiology and Biostatistics, The George Washington University, Washington, DC, United States

Background: The United States Department of Health and Human Services (DHHS) recently identified a set of seven core indicators for monitoring the provision of HIV prevention, care and treatment services. Additionally, the Institute of Medicine (IOM) has also put standard measures in place to assess HIV-related core indicators and quality of care outcomes. With the availability of these measures, population-based outcomes related to HIV care and treatment can more easily be monitored. We sought to examine outcomes along the care continuum among a cohort of HIV-infected persons in care in Washington, DC, a city with one of the highest HIV prevalence estimates in the U.S.

Methodology: The DC Cohort is a longitudinal observational cohort study of HIV-infected persons receiving outpatient care at 13 clinics in Washington, DC. Baseline and longitudinal data on participants enrolled between 1/1/11 and 8/15/13 in the DC Cohort were obtained through electronic medical record abstraction and manual data entry and used to measure select DHHS and IOM measures.

Results: With respect to the DHHS measures, during the period from enrollment to 12-months, 61% of Cohort participants were retained in medical care, 89% were on antiretrovirals (ARVs), 73% were virally suppressed and 8% were homeless or unstably housed. Upon review of the IOM core indicators for HIV care and quality measures, 52% were in continuous care per the IOM definition, 40% were routinely monitored using CD4 counts and 81% of those in continuous care had a CD4 ≥ 350 cells/μl. Only 3% of participants with CD4 counts less than 500 cells/μl had not been started on ARVs and viral load monitoring was routinely performed among 52% of participants. With respect to STD screenings, 5% of participants had been screened for gonorrhea and chlamydia, and 15% were screened for syphilis.

Conclusions: Assessment of these standard HIV care indicators show that although retention in care and routine immunologic and virologic monitoring were moderate, high proportions of participants were receiving antiretroviral therapy with good outcomes as measured by CD4 counts and viral loads. Continued longitudinal analysis will assist in identifying areas for improvement in the quality of HIV clinical care.

999 Potential Impact of Viral Load On ART Eligibility Criteria in Swaziland

Naomi Bock1, Ruth Emerson2, Charles Azih2, Deborah Donnell1, George Bicego1, Velaphi Okello2, Neena Philip4, Rejoice Nkambule3, Yen Duong1, Jessica Justman4
1Centers for Disease Control and Prevention, Atlanta, GA, United States, 2Statistical Center for HIV/AIDS Research and Prevention and the Vaccine and Infectious Disease Institute, Seattle, WA, United States, 3Ministry of Health, Mbabane, Swaziland, 4ICAP-Columbia, Mailman School of Public Health, Columbia University, New York, NY, United States

Background: Antiretroviral therapy (ART) programs implementing “treatment as prevention” need to target not only those who need ART for their own health but also those likely to transmit HIV. Observational studies suggest that HIV transmission risk differs depending on whether the viral load (VL) is above or below 10,000 copies/ml. We describe an assessment of the additional persons who would need ART if VL criteria were added to current CD4 count eligibility criteria in Swaziland.

Methodology: In the Swaziland HIV Incidence Measurement Survey, a nationally representative sample of 18,172 men and women, age 18-49, underwent household-based counselling and rapid HIV testing and provided clinical/demographic information in 2010-11. Among 5802 HIV+ individuals identified during the survey, 1000 were randomly selected to participate in a follow-up visit, with collection of blood for CD4 enumeration via automated flow cytometry and viral load using Roche CAPTAQ HIV-1 Test, V2.0.

Results: Among 949 HIV+ individuals who participated in this sub-study, complete CD4 and VL data were available on 927; in unweighted analysis, 456 of these (49%, 95% CI: 46-52%) did not report ART use. Based on current Swaziland guidelines of ART initiation at CD4 threshold of 10,000 copies/ml were added as a separate ART initiation criterion, the number eligible for ART at CD4<350 would increase by 193 (63%, 95% CI: 57-68%) of the 308 currently ineligible individuals not on ART, an additional 42% (95% CI: 38-47%) of the 456 of the untreated HIV+ sample, and 21% (95% CI: 18-24%) of the entire HIV+ sample.

Conclusions: We provide an estimate of the proportion of additional HIV+ adults who would be ART eligible if a VL threshold were added to CD4 eligibility criteria. Almost one-third of untreated HIV+ persons in our sample are already eligible for ART based on current national CD4 count criteria; effective linkage to ART for them is a program priority. The addition of VL > 10,000 copies/ml to the initiation criteria would increase the ART-eligible proportion of untreated HIV+ adults in our sample by 42%, to almost 75%. These results indicate that the addition of VL to eligibility criteria could modestly increase demand on Swaziland’s ART program. These targeted increases in coverage would be expected to lead to notable reductions in transmission.

Health Insurance for PLWH: Establishing a Baseline To Monitor the Impact of the Affordable Care Act
Baligh R. Yehia1, Allison A. Agwu1, Stephen A. Berry2, Joshua P. Metlay3, Kelly Gebo2
1University of Pennsylvania, Philadelphia, PA, United States, 2Johns Hopkins University, Baltimore, MD, United States, 3Massachusetts General Hospital, Boston, MA, United States

Background: The Affordable Care Act (ACA) will expand Medicaid coverage in most states to include all people with incomes up to 133% of the federal poverty level and will facilitate the purchase of private coverage through health insurance marketplaces. These changes will increase access to care for many people living with HIV (PLWH). Baseline data are needed to monitor the impact of the ACA on access to HIV care. This study examines trends in health insurance coverage (2006-2011) among HIV-infected adults at 13 geographically diverse clinics in the HIV Research Network.

Methodology: Health insurance coverage in each year was categorized as private, Medicaid, Medicare (including dual Medicare/Medicaid), and uninsured/Ryan White. We used multinomial logistic regression to determine if the proportion of patients with each insurance type changed over time, adjusting for age, sex, race/ethnicity, HIV transmission risk, and CD4 count.

Results: Between 2006 and 2011, 37,749 HIV-infected adults were followed for a total of 120,464 person-years. Overall, there were slight fluctuations in the proportion of patients with each insurance type, with no clear trends over time. The proportions of patients with private insurance, Medicare, Medicaid, and uninsured/Ryan White in each year ranged between 17-21%, 18-20%, 33-40%, and 25-30%, respectively. (Figure)

Significant (p<0.01) associations with insurance type were as follows. Private insurance was more common among whites (30%) than Blacks (15%) or Hispanics (10%), and among persons with MSM (26%) than heterosexual (13%) or IDU (10%) risk. Medicare was highest among those ≥65 years old, and lowest among 18-24 year olds (5%). Medicaid was more common among women (50%) than men (31%), and among persons with IDU (53%) than MSM (24%) or heterosexual (42%) risk. Hispanics were more likely to be uninsured (36%) than whites (27%) or Blacks (23%). Similarly, young adults (18-24 year olds) were more often uninsured (51%) than persons aged 65 years or older (7%).

Conclusions: Health insurance coverage was stable between 2006 and 2011, providing a firm baseline for assessing the impact of the ACA. Disparities in health insurance coverage exist, particularly for racial/ethnic minorities and younger adults. Monitoring how health insurance coverage changes will be critical to ensuring that PLWH benefit from health reform and for defining the future role of the Ryan White Program.

Atypical Clinical Presentations Occur in One Third of 293 Patients With a Primary HIV-1 Infection
Dominique L. Braun, Roger Kouyos, Belinda Balmer, Christina Grube, Rainer Weber, Huldrych Günthard
Division of Infectious Diseases and Hospital Epidemiology, University Hospital Zurich, University of Zurich, Zurich, Switzerland

Background: Proportion and disease-spectrum of atypical clinical presentations in primary HIV-Infection (PHI) has not systematically been studied. Unusual presentation of PHI may lead to delayed diagnosis with impact on transmission.

Methodology: Between January 2002 and June 2012 we prospectively enrolled 293 individuals with a well-documented PHI in the Zurich Primary HIV Infection Study, which is an open label, non-randomized, observational, single-center study. PHI was classified as “acute” (acquisition of infection during the last 3 months) or “recent” (acquisition during the last 6 months). At the first visit, a detailed history of symptoms and clinical signs of PHI, a physical examination and standard and specific HIV laboratory parameters were obtained. “Typical” ARS was determined in case of documented or reported fever (temperature > 38°C) plus at least one symptom OR ≥2 symptoms (in absence of fever) considered as ARS symptoms in literature. “Atypical presentation” was determined by study-physicians based on patient’s medical history, review of medical chart, lack of any ARS symptoms OR a single symptom only. The date of infection (EDI) for each patient was estimated integrating all available clinical and laboratory data. Time to diagnosis was calculated based on EDI and date of first positive screening test.

Results: We analysed 293 individuals with PHI, including 271 males. PHI was classified in 245 (84%) individuals as “acute” and in 48 (16%) as “recent”. PHI manifested as typical ARS in 203 (69%) of 293 patients. Overall, PHI presented atypically or with an opportunistic infection (OI) in 90 (31%) of 293
patients, 16 (18%) of them were fully asymptomatic. Patients with atypical PHI presented with a broad spectrum of diseases (table 1). Gastrointestinal tract and central nervous system were the most prevalent organ systems for atypical PHI and OI’s. Atypical presentation did not lead to a significantly delayed diagnosis (median time EDI to first positive test without symptoms: 42 days [95% Bootstrap confidence interval 18.4, 65.6]; atypical presentation: 32 days [25.8, 38.2], typical ARS: 29 days [24.8, 33.2]; p = 0.13), but a surgical intervention was required in 6 (6.5%) of 90 patients.

Conclusions: Atypical presentations and OI’s occur in a substantial proportion of patients with PHI, however, did not result in delayed diagnosis. This may be explained by the severe clinical presentation of these patients leading to a low threshold for HIV testing.

**Evaluating New Definitions of Acute and Early HIV Infection From HIV Surveillance Data**

Susan E. Buskin, Neway G. Fida, Amy B. Bennett, Matthew R. Golden, Joanne D. Stekler

1 Prevention Division, Public Health - Seattle & King County, Seattle, WA, United States, 2 Epidemiology Department, University of Washington, Seattle, WA, United States, 3 Department of Medicine, University of Washington, Seattle, WA, United States, 4 Division of Allergy & Infectious Diseases, University of Washington, Seattle, WA, United States

**Background:** The Centers for Disease Control and Prevention plans adding acute (Stage 0) infection (AHI) to the HIV staging system. We evaluated our ability to categorize early and AHI using Public Health - Seattle & King County surveillance data.

**Methodology:** Cases of AHI were identified by pooled nucleic acid amplification testing (NAAT), conducted for men who have sex with men (MSM) with negative antibody tests at King County testing sites since 2003. We calculated inter-test intervals (time from last negative to first positive test) and interpretations of “recent” from the serologic algorithm for recent HIV seroconversion (STARHS) to create surveillance definitions of early and AHI: AHI included inter-test intervals of zero days and 0-30 days; early HIV diagnoses were inter-test intervals of 0-180 days or a STARHS recent result. Last negative HIV tests were lab reports to the HIV/AIDS Reporting System (eHARS) or patient/provider data collected for HIV Incidence Surveillance. Sensitivity was calculated as the proportion of cases correctly identified as early or AHI by surveillance definitions relative to the gold standard of AHI defined by NAAT.

**Results:** Between 2005 and 2011 2,156 individuals were diagnosed with HIV in King County, including 1,556 (72%) MSM. Of 1,223 individuals with a known testing history (57% of all diagnoses), 377 (31%) tested negative for HIV within six months of their HIV diagnosis. Among 1,104 with STARHS results (51% of new cases), 39% were STARHS recent. Of the 47 MSM with AHI identified by NAAT, 33 (70%; 95% CI = 55-82%) had an inter-test interval of six months or less (Table). Over one third (36%) of the 47 AHI cases had documentation of their negative antibody test on the same day in eHARS. Four of these were documented lab test results and 13 came from other sources. Of the 47, 18 (38%) AHI cases had STARHS testing. Of these, 94% (95% CI = 70-100%) were STARHS recent; the single non-recent result was from a one month post-diagnosis specimen.

**Conclusions:** Early and AHI cases were frequently missed in eHARS because negative antibody tests weren’t reported. Similarly, STARHS results were not available for half of all recently diagnosed individuals and a larger proportion of AHI diagnoses. Successful implementation of the revisions to the HIV staging system will require that laboratories report negative HIV tests obtained concurrently with reactive HIV tests.

**Association Between Number of Acute Retroviral Symptoms and Extended High Viremia by HIV-1 Subtype**

1 Department of Epidemiology, The University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 2 International AIDS Vaccine Initiative, New York, NY, United States, 3 Department of Epidemiology and Biostatistics, University of California at San Francisco, San Francisco, CA, United States, 4 Project San Francisco, Kigali, Rwanda, 5 Medical Research Council / Uganda Virus Research Institute, Entebbe, Uganda, 6 Zambia Emory Research Project, Lusaka and Copperbelt, Zambia, 7 Emory University, Atlanta, GA, United States, 8 Kenya AIDS Vaccine Initiative, Nairobi, Kenya, 9 Kenya Medical Research Institute, Kilifi, Kenya, 10 University of Oxford, Headington, United Kingdom

**Background:** Prompt identification of persons with acute HIV infection, particularly those likely to have high viral loads after acute HIV, presents important transmission prevention opportunities. In a large study of HIV-1 seroconverters across 9 sites in Africa, we sought to determine whether the number of signs and symptoms of acute retroviral syndrome (ARS) predicted extended high viremia (mean viral load >= 5 log10 copies/ml 130-330 days after infection) in HIV-1 subtypes A, C, and D.

**Methodology:** Adults who acquired HIV-1 infection in a multicenter HIV-1 incidence study were enrolled in a sub-study assessing ARS, immune progression, and viral load dynamics. Estimated date of infection (EDI) was based on a positive plasma viral load or p24 antigen test prior to seroconversion, or the mid-point between a negative and positive HIV-1 serologic test. ARS signs and symptoms were assessed at sub-study enrollment, and viral load was assessed monthly for 3 months post-EDI and quarterly thereafter. “Extended high viremia” was defined as mean pre-ART viral load >=5 log10 copies/ml
130-330 days post-EDI. We used log-binomial regression to examine associations by subtype between the number of ARS symptoms and extended high viremia, controlling for sex.

Results: Among the 130 volunteers (38%) with pol-derived subtype A infection, extended high viremia prevalence increased linearly with the number of ARS signs/symptoms; those with 2-7 and >=8 symptoms were 1.9 (95% confidence interval: 1.4, 2.8) and 3.7 (1.8, 7.7) times as likely to have extended high viremia vs. those with 0-1 symptom (p=0.03 and 0.003, respectively; Figure). Among the 153 subtype-C volunteers (45%), those with 2-7 symptoms were 2.1 (1.3, 3.4) times as likely to have extended high viremia vs. those with 0-1 symptom (p=0.02; Figure). Among the 59 subtype-D volunteers (17%), extended high viremia prevalence was similar in those with 2-7 vs. 0-1 symptom (p=0.93). In subtypes C and D, 0% of those with >=8 symptoms had extended high viremia (Figure); however, measures were imprecise because few subtype-C and D volunteers reported extreme numbers of symptoms.

Conclusions: In this multi-site African cohort, the relationship between number of ARS signs/symptoms and extended high viremia varied appreciably across subtypes, suggesting potential differences by subtype in pathogenicity, immune response, and the predictive power of number of symptoms in identifying newly infected persons who likely will have extended high viremia.

Figure. Prevalence of extended high viremia (mean log_{10} viral load ≥ 5 log_{10} 130-330 days after the estimated date of infection) by subtype and number of acute retroviral syndrome (ARS) symptoms. Numerator and denominator for each proportion are shown in parentheses.

1004 Targeted Screening of Young Adults for Acute HIV-1 Infection at Care Seeking in Kenya

Eduard J. Sanders¹,², Peter Mugo¹, Henrike A. Prins¹, Elizabeth Wahome¹, Alexander Thiong'o², Grace Mwasigadi¹, Elisabeth M. Van der Elst¹, Anisa Omar³, Adrian D. Smith⁴, Susan M. Graham¹, ⁵, ⁶
¹Clinical Sciences, KEMRI-Wellcome Trust Research Programme, Kilifi, Kenya, ²Nuffield Department of Clinical Medicine, University of Oxford, Oxford, United Kingdom, ³County Health Department, Ministry of Health, Kilifi, Kenya, ⁴Public Health Department, University of Oxford, Oxford, United Kingdom, ⁵University of Washington, Seattle, WA, United States

Background: Up to 40% of new HIV-1 infections derive from sexual contact with patients with acute HIV-1 infection (AHI) who frequently seek care for symptoms prior to seroconversion. We assessed whether AHI could be detected in young adults seeking urgent care at pharmacies (PR) and health facilities (HF) in Coastal Kenya.

Methodology: Young adults (<30 years of age) meeting one of four predetermined AHI risk criteria: (1) fever (≥37.5 °C axillary), (2) sexually transmitted disease symptoms (STD), (3) diarrhea, or (4) body pains and multiple partners in the last 2 months were referred from 5 PR and identified at 5 HF. Prevalent HIV-1 was determined by nationally recommended serial HIV-1 testing (2 rapid tests) in all patients assessed for AHI-criteria. HIV-1-negative or -discordant patients who accepted p24 antigen testing were randomized to reminders or no reminders and invited for repeat rapid testing 2-4 weeks following enrollment (Clinicaltrials.gov, NCT01876199). AHI was diagnosed by a positive p24 antigen test and subsequent seroconversion. Febrile HIV-1-negative patients were also screened for malaria using a rapid test, with PCR confirmation of positives.

Results: Of 6527 young adult outpatients, 3602 (55.2%) were screened for AHI risk criteria and tested for prevalent HIV-1. Overall, 139 (3.9%) patients had undiagnosed prevalent HIV-1, of whom 36 (25.9%) had never tested, 100 (71.9%) were previously negative, and 3 (2.2%) had an unknown status. The prevalence of undiagnosed HIV-1 among patients meeting AHI risk criteria was 7.6% (68/896) vs. 2.6% (71/2706) among those who did not (p<0.001). This finding did not differ by source of referral (PR vs. HF). AHI was diagnosed in 6 of 507 HIV-1-negative or -discordant patients (prevalence 1.2%, 95% confidence interval (CI): 0.4%-2.6%), including 2 patients referred from PR. Of these 6 AHI cases, 4 were diagnosed among the 242 patients with fever (prevalence 1.7%, 95% CI: 0.5%-4.2%), vs. 2 among 265 non-febrile patients (prevalence 0.7%, 95% CI: 0.0%-2.7%). Malaria was diagnosed in 4 of the 242 febrile patients (prevalence 1.7%). No additional HIV-1 seroconversions were detected at repeat HIV-1 testing of 243 (47.9%) participants who returned for repeat rapid testing. Return rates were higher among patients who received reminders (58.5% vs. 41.1%, p<0.001).

Conclusions: We found a high burden of undiagnosed prevalent and acute HIV-1 in young adults seeking urgent care at PR and HF in an area endemic for malaria. Reminding patients about follow-up testing was modestly efficacious. AHI prevalence was highest among young febrile adults. An AHI detection strategy targeting febrile young adults seeking care at PR and HF is feasible and could potentially be used to target Treatment as Prevention programs.
1005 Independent Evaluation of Predicate Incidence Assays for HIV Surveillance

Reshma Kassanjee1, Christopher Pilcher2, Sheila Keating3, Shelley Facente4, Matt Price4, Jeffrey Martin2, Susan Little5, Alex Welte1, Michael Busch3, Gary Murphy6, Consortium for the Evaluation and Performance of HIV Incidence Assays (CEPHIA)

1The South African DST/NRF Centre of Excellence in Epidemiological Modelling and Analysis (SACEMA), Stellenbosch University, Stellenbosch, South Africa, 2University of California San Francisco, San Francisco, CA, United States, 3Blood Systems Research Institute, San Francisco, CA, United States, 4Department of Medical Affairs, International AIDS Vaccine Initiative (IAVI), New York City, NY, United States, 5Department of Medicine, University of California San Diego, La Jolla, CA, United States, 6Health Public England, London, United Kingdom

Background: Accurate estimates of HIV incidence are needed to assess epidemics, calibrate models, and design and evaluate interventions. The cross-sectional use of biomarker-based Tests for Recent HIV Infection (TRIs) in principle offers affordable, low-bias options for incidence estimation. To date, there has been no independent, directly comparative benchmarking of candidate TRIs.

Methodology: A repository was assembled comprising replicate plasma samples from 5641 specimens representing 2007 subjects from studies in Africa, Brazil and the United States, with suitably characterized longitudinal subject information (estimated exposure dates, detailed treatment and clinical history, viral load, CD4 counts). Five TRIs (BED, Limiting Antigen (LAg), Detuned Vitros, Vitros Avidity and Biorad Avidity), previously assessed on a 250 sample ‘Qualification Panel’, were evaluated using a clade diverse 2500 member ‘Evaluation Panel’. Using developers’ previously published recent/non-recent discrimination criteria, frequency estimation and regression yielded estimates of the Mean Duration of Recent Infection (MDRI - mean time, within one year post estimated exposure, that subjects return recent results), False-Recent Rate (FRR - proportion of recent test results among patients at least one year post infection) and assay reproducibility (CoV - coefficient of variation of assay reading). FRR was calculated by time since infection for untreated patients, and separately by ARV treatment status.

Results: Table 1 shows primary performance characteristics of the incidence assays. FRR is reported by treatment status and in a hypothetical population with 30% of positives ART suppressed. Treated versus untreated FRR differences all have p<0.001.

Conclusions: This is the first independent evaluation of predicate incidence assays. According to developers’ published protocols, none appears suitable, in stand-alone form, as a widely applicable incidence surveillance tool. As viral suppression drives false recent results, optimized use of serologic assays, using low viral load as indicative of non-recent infection, could yield practical TRIs. Work is on-going to 1) evaluate additional assays, 2) optimise multiple biomarker algorithms, 3) estimate FRR with realistic population representative distributions of clinical stages, and 4) maintain and expand the repository to support new work including biomarker discovery.

1006 Performance of the Limiting Antigen-Avidity EIA for Use With Dried Blood Spot Specimens

Erin K. Rottinghaus, Trudy Dotbs, Bharat S. Parekh, Yen T. Duong

Centers for Disease Control and Prevention, Atlanta, GA, United States

Background: The Limiting Antigen-Avidity EIA (LAg-Avidity EIA) is a newly developed HIV-1 incidence assay that was recently validated for plasma specimens for estimation of HIV-1 incidence, a critical end-point measurement to determine the impact of HIV programs. The LAg-Avidity EIA was developed for global use and is available as a kit for use with serum/plasma from two manufacturers. Collection of liquid specimen, processing, storage, and transport are challenging in resource-limited countries and dried blood spots (DBS) are the specimen of choice for surveillance activities. Thus, there is an urgent need for the development and qualification of a LAg-Avidity EIA for use with DBS specimens. Here, we present the evaluation of the Maxim LAg-Avidity DBS EIA for use specifically with DBS specimens.
Methodology: A total of 447 matched plasma and DBS specimens were used for this evaluation. Of these, 133 plasma units were purchased from Boca Biosciences (Coconut Creek, FL) and 90 were from Seracare Life Sciences (Milford, MA). Matched DBS were prepared by spotting 100 μl of mock blood (plasma mixed 1:1 with packed red blood cells) onto Whatman 903 filter paper (Whatman plc, United Kingdom). The remaining 224 specimens were collected as unlinked remnant whole blood specimens from HIV-positive patients at an Atlanta-based clinic and matched DBS and plasma were prepared by spotting whole blood onto Whatman 903 filter paper followed by plasma separation. For DBS specimens, 500 μl of specimen diluent was used to elute antibodies overnight from a single 6 mm punch and 100 μl was added to the assay plate. DBS controls were used when testing DBS specimens. All other assay steps remained the same. All plasma and DBS specimens were tested independently by two operators using the Maxim HIV-1 LAg-Avidity EIA (Maxim Biomedical, Rockville, MD) according to the manufacturer’s instructions.

Results: Correlation between the DBS and plasma specimens was excellent (r²=0.94) with 85 specimens classifying as recent and 362 as long-term infections with both specimen types (overall agreement 98.6%, kappa = 0.956). DBS kit controls were highly reproducible across 26 runs performed by two operators with inter- and intra-run coefficients of variation (%CV) for the low positive control (LPC) and high positive control (HPC) <10%, similar to plasma controls. Inter-operator normalized optical density (ODn) variability between two operators was <10%.

Conclusions: This evaluation demonstrates the Maxim LAg-Avidity EIA performs similarly with the DBS or serum/plasma specimens, allowing DBS specimens to be used in surveillance activities for the estimation of HIV incidence. This comprehensive evaluation will further facilitate implementation of LAg-Avidity EIA for cross-sectional incidence estimates.

1007 The Impact of HIV Subtype On Cross-Sectional HIV Incidence Assays in Rakai, Uganda

Andrew F. Longosz1, David Servadda2, 3, Fred Nalugoda2, Godfrey Kigozi2, Veronica Franco4, Ronald H. Gray2, 3, Thomas C. Quinn1, 4, Susan H. Eshleman1, Oliver Lelyaendecker1, 4

1NIAID, National Institutes of Health, Baltimore, MD, United States, 2Makerere University School of Public Health, Kampala, Uganda, 3Rakai Health Sciences Program, Rakai, Uganda, 4The Johns Hopkins University School of Medicine, Baltimore, MD, United States, 5The Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

Background: We compared the impact of viral subtype on the specificity of three cross-sectional incidence assays by testing samples from Ugandan individuals infected 2+ years.

Methodology: Samples were obtained from 510 adults (212 subtype A, 298 subtype D) enrolled in the 2008-2009 Rakai Community Cohort Study (RCCS) who were infected for 2.2 to 14.5 years (median 5.4 years). These individuals were not virally suppressed and were antiretroviral drug treatment-naive. The samples were tested with three assays: (1) the LAg-Avidity enzyme immunoassay (LAg-Avidity, reported as normalized optical density (OD-n)), (2) an avidity assay based on the BioRad 1/2+0 ELISA (BioRad-Avidity, reported as avidity index [AI]), and (3) the BED capture enzyme immunoassay (BED-CEIA, reported as OD-n). The performance of these three assays was evaluated using various assay cutoff values (LAg-Avidity: ≤1.5 OD-n; BioRad-Avidity: ≤40% AI; BED-CEIA: ≤0.8 OD-n).

Results: The percentage of samples misclassified by each assay as assay positive (below the assay cutoff) were: LAg-Avidity: 3.3% (17/510, 95% CI: 2.0-5.0), BioRad-Avidity: 12.9% (66/510, 95% CI: 10.0-16.0), BED-CEIA: 13.7% (70/510, 95% CI: 11.0-17.0). The misclassification frequencies of the assays for subtype A and D samples were: LAg-Avidity: 1.9% (4/212) for subtype A, 4.4% (13/298) for subtype D, p=0.13; BioRad-Avidity: 1.9% (4/212) for subtype A, 20.8% (62/298) for subtype D, p<0.01; BED-CEIA 11.8% (25/212) for subtype A, 15.1% (45/298) for subtype D, p=0.29. The mean LAg-Avidity result (OD-n) was higher for subtype A than D (4.54±0.95 vs. 3.86±1.26, p<0.01). The mean BioRad Avidity result (AI) was higher for subtype A than D (88.9±12.5% vs. 75.1±30.5, p<0.01). The mean BED-CEIA result (OD-n) was similar for the two subtypes (2.2±1.2 and 2.2±1.3, p<0.9).

Overall, 1.4% (7/510, 95% CI: 1.0-3.0) of the samples were misclassified by all three assays; 2.2% (11/510, 95% CI: 1.0-4.0) were misclassified by both LAg-Avidity and BED-CEIA; 2.6% (13/510, 95% CI: 1.0-4.0) were misclassified by LAg-Avidity and BioRad-Avidity, and 3.9% (20/510, 95% CI: 8.0-20.0) were misclassified by BED-CEIA and BioRad-Avidity.

Conclusions: The LAg-Avidity assay (used with a cutoff ≤1.5 OD-n) had the lowest frequency of misclassification in this Ugandan population. However, use of this assay is not recommended in areas where subtype D circulates because of differential misclassification by subtype.

1008 Incorrect Identification of Recent HIV Infection Using a LAg-Avidity Assay in Adults in the US

Andrew F. Longosz1, Ron Brookmeyer2, Shruti Mehta1, Greg D. Kirk3, Joseph B. Mangolick3, Joelle Brown1, Thomas C. Quinn1, 4, Susan H. Eshleman1, Oliver Lelyaendecker1, 4

1Laboratory of Immunoregulation, Division of Intramural Research, National Institutes of Health, Baltimore, MD, United States, 2Department of Biostatistics, University of California Los Angeles, Los Angeles, CA, United States, 3Department of Epidemiology, The Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, 4Department of Molecular Microbiology and Immunology, The Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

Background: The United States (US) Centers for Disease Control recently introduced the Limited Antigen-Avidity enzyme immunoassay (LAH-Avidity assay), a new, commercially-available, cross-sectional HIV incidence assay. We analyzed factors associated with misclassification by the LAH-Avidity assay among men who have sex with men and persons who inject drugs living in the US with long-term (2+ years) infection.

Methodology: Samples were obtained from the Multicenter AIDS Cohort Study (MACS), and AIDS Linked to the IntraVenous Experience (ALIVE) cohorts (1089 samples from 666 individuals: 612 samples collected 2-4 years after seroconversion and 477 samples collected 5-8 years after seroconversion). Paired samples from both time points were available for 423 (63.5%) of the 666 individuals. Samples were tested with the LAH-Avidity assay using an assay cutoff of ≤1.5 normalized optical density units (OD-n). Samples with results ≤1.5 OD-n were considered to be misclassified.
Results: Overall, 4.8% (52/1089) of the samples were misclassified by the LAg-Avidity assay. The percentages of samples that were misclassified for different sample subsets were as follows. Overall: 4.8% (52/1089); individuals who reported that they were not on antiretroviral treatment (ART): 3.3% (26/790); individuals with viral loads >400 copies/mL: 1.8% (16/884); individuals with viral loads >400 copies/mL who also had CD4 counts >200 cells/ul: 1.4% (10/705), 95% CI: 0.68-2.60). Age, race, gender and mode of HIV acquisition were not associated with misclassification. In an adjusted analysis, viral load <400 copies/mL (adjusted odds ratio [aOR]: 3.72, 95% CI: 1.61-8.57), CD4 <50 cells/ul (aOR: 5.41, 95% CI: 1.86-15.74) and have a low LAg-Avidity result (≤1.5 OD-n) from an earlier time point (aOR: 5.60, 95% CI: 1.55-20.25) were significantly associated with misclassification. Self-reported ART was not associated with misclassification in the adjusted analysis.

Conclusions: Individuals who are misclassified by the LAg-Avidity assay are likely to be misclassified for the duration of their infection. The current recommendations for the LAg-Avidity assay indicate that individuals on HAART and elite suppressors and AIDS (CD4 <200 cells/ul) should be excluded from analysis does not completely remove all sources of misclassification among long-term infected individuals.

Session P-W7 Poster Session
Thursday March 6, 2014, 2:30 PM–4:00 PM  Exhibit Hall D
Disease Progression/Mortality

1009 Increasing Viral Suppression and Declining HIV/AIDS and Mortality in the Era of Expanded Treatment
Susan E. Buskin1, 2, Amy B. Bennett1, Julia C. Dombrowski1, 3, Matthew R. Golden1, 3
1Prevention Division, Public Health, Seattle & King County, Seattle, WA, United States, 2Epidemiology Department, University of Washington, Seattle, WA, United States, 3Department of Medicine, University of Washington, Seattle, WA, United States

Background: U.S. national data suggest that the number of new HIV diagnoses is roughly stable. However, within that stability, there may be substantial heterogeneity, with divergent trends occurring in different parts of the U.S. and in sub-populations within geographical areas.

Methodology: We used data from the U.S. Census and the King County, WA HIV/AIDS Reporting System (eHARS) 2003-2012 to assess trends in the rate of new HIV diagnoses and AIDS diagnoses in the general population, and in age-adjusted mortality rates among people diagnosed with HIV infection (PLWHA). Trends in viral suppression, defined as any plasma viral load (VL) <200 in a year, were evaluated between 2006 and 2012, the period during which all VL results were reportable in WA State. We assessed trends using Chi-square testing.

Results: Between 2003 and 2012, the rate of new HIV diagnoses decreased from 19.8 to 14.8 per 100,000 residents (decline of 25%); death rates decreased from 3.2 to 0.9 per 100 PLWHA (decline of 72%); and AIDS diagnosis rates declined 53% from 14.7 to 6.9 per 100,000 (p<0.0001 for all three trends; see figure). Among 6,801 individuals with any laboratory results reported to HARS 2006 through 2013, viral suppression increased from 46% to 85% (p<0.0001). Rates of new HIV diagnoses significantly dropped in both MSM and IDU, and among Hispanics and U.S. born blacks. We did not observe any significant change in the rate of new HIV diagnosis among women, Asians, foreign-born individuals, or among MSM who injected drugs. HIV diagnosis rates significantly declined among individuals aged 35 to 44 years but not younger or older individuals. Death rates declined in both MSM and IDU (p<0.001 and p=0.007 respectively); the mortality rate among MSM was roughly half that for IDU. AIDS diagnosis rates declined in both MSM and IDU (p<0.001 for both) though the rate of decline was steeper among MSM relative to IDU.

Conclusions: The rates of new HIV diagnosis, AIDS diagnoses and mortality in persons living with HIV in King County, WA have significantly declined over the last decade. These changes have occurred concurrent with a dramatic increase in HIV viral suppression, and have affected diverse populations in our area, including racial and ethnic minorities.
1010  BMI and CD4+ T-Cell Recovery at 12 Months Among Adults Initiating ART in the United States and Canada

John R. Koethe1, Cathy Jenkins2, Bryan Lau3, Bryan E. Shepherd2, Michael J. Silverberg2, Aaron J. Blashill2, Aranka Anema2, Amanda Willig2, Samuel E. Stinnette2, Timothy R. Sterling1, North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD)

1Infectious Diseases, Vanderbilt University, Nashville, TN, United States, 2Biostatistics, Vanderbilt University, Nashville, TN, United States, 3Infectious Diseases, Johns Hopkins University, Baltimore, MD, United States, 4Kaiser Permanente Northern California, Oakland, CA, United States, 5Harvard University, Boston, MA, United States, 6British Columbia Centre For Excellence in HIV/AIDS, Vancouver, BC, Canada, 7University of Alabama at Birmingham, Birmingham, AL, United States, 8University of North Carolina, Chapel Hill, NC, United States

Background: Adipose tissue affects aspects of the cellular immune system, but prior studies have differed on whether a higher body mass index (BMI) promotes increased CD4+ T-cell recovery on antiretroviral therapy (ART). We used the multi-site NA-ACCORD dataset to analyze the relationship between pre-treatment BMI and 12 month CD4+ T-cell recovery among adults initiating ART and achieving virologic suppression in the United States and Canada.

Methodology: We included treatment naïve adults initiating ART between 1998 and 2010 in NA-ACCORD who maintained HIV RNA levels <400 copies/ml for at least 6 months after ART initiation. The association between pre-treatment BMI and CD4+ T-cell change after 12 months of ART was assessed using multivariable regression models adjusted for age, race, baseline CD4+ count and HIV RNA level, year of ART initiation, protease inhibitor therapy, and clinical site. All continuous variables were fit using restricted cubic splines.

Results: 14,084 patients from 13 cohorts contributed data; 83% were male, 57% were non-white, median age was 40 years (IQR 33, 47), median baseline CD4+ T-cell count was 241 cells/µl (IQR 94, 377), and median baseline log10 viral load was 4.7 copies/ml (IQR 3.9, 5.3). 8,381 participants (70%) maintained virologic suppression for ≥6 months; of these, 4,422 (53%) had a BMI <25 kg/m², 2,713 (32%) were overweight (BMI 25.0-29.9 kg/m²), and 1,246 (15%) were obese (BMI ≥30 kg/m²). Pre-treatment BMI was associated with 12 month CD4+ T-cell change (p<0.001), but the relationship was non-linear (p=0.006). Compared with a reference of 25 kg/m², a BMI of 30 kg/m² was associated with a 26.0 cells/µl (95% CI: 9.7, 42.4) greater CD4+ T-cell count increase among women and a 11.9 cells/µl (95% CI: 5.0, 18.8) increase among men at 12 months. At a BMI over 30 kg/m² the observed benefit was attenuated among male patients to a greater degree than among female patients. Lower age and baseline viral load were also associated with a more robust 12 month gain (p<0.001 for both). Inferences were similar when the model was adjusted for prior AIDS-defining events, injection drug use, and hepatitis C co-infection among the subset with available data.

Conclusions: A BMI of approximately 30 kg/m² at ART initiation was an inflection point associated with greater CD4+ T-cell recovery at 12 months compared to higher or lower BMI values. This finding may indicate that relative adiposity affects peripheral CD4+ T cell recovery on ART, which should be explored further in translational studies to understand the mechanisms and potential therapeutic implications.

1011  Impact of Smoking On Life Expectancy Among HIV-Infected Individuals: The ART Cohort Collaboration

Marie Helleberg1, Margaret T. May2, Jonathan A. C. Sterne2, Niels Obel1, for the ART-CC

1Department of Infectious Diseases, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark, 2School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom

Background: Since the introduction ART non-AIDS related mortality rates (MR) in treated HIV positive people have exceeded AIDS-related MR, and the impact of smoking on life expectancy may have become substantial.

Methodology: We estimated associations of smoking with mortality among treated HIV-infected patients, whose presumed transmission was not via IDU, enrolled in 8 cohorts in Europe and North America (ART Cohort Collaboration). Start of follow up (baseline) was the later of date of ascertainment of smoking status and 1 year after ART initiation. Procedures for standardized coding of deaths were adapted from the CoDe protocol. We used abridged life tables to estimate life expectancy (average years remaining to be lived). Life years lost to HIV were estimated by comparing life expectancies of HIV-infected individuals with the French background population, adjusting for smoking frequency. Excess MRs were estimated by subtracting MRs of ever from never smokers and of HIV-infected individuals from the French background population, adjusting for smoking frequency. Numbers of life years lost were estimated by similar subtraction of life expectancies.

Results: Of 17,995 individuals followed for 79,760 person-years (PY) 10,767 (60%) were ever smokers MR ratios (MRR) were 1.80 (95%CI 1.47-2.21) comparing ever with never smokers and 1.67 (1.04-2.63) comparing...
Standardized Mortality Ratios Among Drug Users in Amsterdam Differ by HCV and HIV Infection Status

Daniela K. van Santen1, Jannie J. J. van der Helm, Bart P. X. Grady1, 2, Anna S. de Vooi3, Mirjam E. E. Kretzschmar4, 5, Ineke G. Stolte1, Maria Prins1, 2

1Research, Public Health Service of Amsterdam, Amsterdam, Netherlands, 2Center for Infection and Immunology Amsterdam (CINIMA), Academic Medical Center (AMC), Amsterdam, Netherlands, 3University Medical Center Utrecht, Julius Centrum, Utrecht, Netherlands, 4Centre for Infectious Disease Control, National Institute of Public Health and the Environment, Bilthoven, Netherlands

Background: The start of a major heroin epidemic in the 1960s was followed by an hepatitis C (HCV) and HIV epidemic among drug users (DU). Therefore, harm reduction interventions (e.g. needle exchange programs) were introduced in Amsterdam during the 1980s. Over time effective HIV and HCV treatment also became available. We hypothesize that because of these health related interventions, DU have reached mortality rates more comparable to the general Dutch population in recent calendar periods. Hence, we investigated temporal trends in mortality rates among DU compared to the general population using Standardized Mortality Ratios (SMR). We also explored whether SMR differed by HIV/HCV infection status and cause of death.

Methodology: Using longitudinal data from the Amsterdam Cohort Studies among 1,263 DU (1985-2012), we estimated all-cause and cause-specific SMR. Four groups of causes of death were addressed: natural, non-natural, liver- and HIV-related deaths. SMR were standardized for calendar period, (<1990; 1990-1996; 1997-2000; 2001-2005 and >2005), age group (20-34, 35-49 and 50-64) and sex. We further obtained the SMR per serological group (HCV mono-, HIV mono-, HCV/HIV co-infected and un-infected for HCV and HIV). Univariable and multivariable Poisson models offsetting the natural logarithm of expected deaths were used to estimate SMR and p-values.

Results: Among 1228 eligible participants, the median baseline age was 41 years (IQR 34-47), 12% (n=122) were women, and 24% (n=293) had hepatitis C co-infection. In the median follow-up time of 6 years (IQR 3-10), a total of 140 (11%) deaths were reported. After 1 year of ART, the median (IQR) VACS and restricted index scores were 36 (32-44) and 10 (10-23), respectively. Overall, compared to the restricted index, the VACS index showed greater test discrimination of the VACS vs. restricted index for all-cause mortality during follow-up.

Of 1228 eligible participants, the median baseline age was 41 years (IQR 34-47), 12% (n=122) were women, and 24% (n=293) had hepatitis C co-infection. In the median follow-up time of 6 years (IQR 3-10), a total of 140 (11%) deaths were reported. After 1 year of ART, the median (IQR) VACS and restricted index scores were 36 (32-44) and 10 (10-23), respectively. Overall, compared to the restricted index, the VACS index showed greater test discrimination of the VACS vs. restricted index for all-cause mortality during follow-up.
Conclusions: The VACS index is a better predictor of mortality compared to HIV markers alone within this British Columbian cohort; however, its discrimination varies within certain socio-demographic groups.

1015 Impact of Low-Level Viremia On Clinical and Virological Outcomes in Treated HIV Infected Patients

Marie-Anne Vandenbende1, Suzanne Ingle2, Margaret May3, Matthias Cavassini3, Amanda Mocroft4, Peter Reiss5, Janet Tate6, Heidi Crane7, Jonathan Sterne8, Geneviève Chêné9, on behalf of the Antiretroviral Therapy Cohort Collaboration (ART-CC)

1Epidémiologie-Biostatistique, Université Bordeaux, Centre INSERM U897, ISPED, Bordeaux, France, 2School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom, 3Lausanne University Hospital and University of Lausanne, Lausanne, Switzerland, 4Research Department of Infection and Population Health, UCL Medical School, London, United Kingdom, 5Academic Medical Center, Amsterdam Institute of Global Health and Development, Amsterdam, Netherlands, 6Yale University School Of Medicine, VA Connecticut Healthcare System, New Haven, CT, United States, 7Center for AIDS Research; University of Washington, Seattle, WA, United States

Background: The goal of antiretroviral therapy (ART) is to maintain undetectable viremia but the impact, particularly on clinical outcomes, of low-level viremia (LLV) between 50 and 500 cp/ml remains unknown.

Methodology: We analysed data from 19 cohorts in Europe and North America contributing to the ART Cohort Collaboration (ART-CC). Included patients started ART (“baseline”) with either NRTI or a PI (atazanavir, darunavir or lopinavir) boosted with ritonavir, and continued ART for at least 6 months, achieving viral load (VL) <50 cp/ml 3-9 months after initiating ART (“virological suppression”, VS). LLV50-199 was defined as at least 2 consecutive VL between 50 and 199 cp/ml and LLV200-499 as 2 consecutive VL between 50 and 499 cp/ml, with at least one between 200-499 cp/ml, after VS. All VL assays had 50 cp/ml lower limit of detection.

We used Cox models stratified by cohort to estimate crude and adjusted hazard ratios (HR) for associations of LLV (50-199 cp/ml and 200-499 cp/ml, compared to <50cp/ml) with death, first AIDS event and first virological failure (VF, defined as 2 consecutive VL ≥500 cp/ml or 1 VL ≥500 cp/ml followed by modification of ART regimen). Adjustments were for baseline age, gender, ART regimen, transmission group, CD4 count, VL and AIDS, and period of ART initiation. LLV categories were considered as time-updated variables.

Results: Among 17853 patients (mean age 40 years, male 76%, mean baseline CD4 238 cells/µL, NRTI-based regimen 59%), 619 (3.5%) experienced at least one episode of LLV50-199 with no LLV200-499 (mean total duration: 6.8 months) and 481 (2.7%) at least one episode of LLV200-499 (mean total duration: 8.6 months). There were 478 deaths, 554 first post-ART AIDS events and 1022 VF in 68018 person-years follow-up.

LLV200-499 was strongly associated with higher risk of VF (adjusted HR 4.15, 95% CI 3.19-5.39). LLV50-199 was weakly associated with VF (aHR 1.40, 0.96-2.02). There was little evidence that LLV50-199 or LLV200-499 were associated with AIDS (aHR 1.13, 0.79-1.61 and 0.91, 0.61-1.28, respectively) or death (aHR 1.20, 0.79-1.83 and 1.12, 0.73-1.71 respectively), compared with prolonged suppression. Neither type of ART regimen (NNRTI-versus PI/r-based) nor cumulative duration of LLV were associated with virological or clinical outcomes.

Conclusions: Among patients virologically suppressed 3-9 months after starting ART, LLV200-499 was strongly associated with virological failure, but not with AIDS events or death. LLV50-199 had little impact on virological or clinical outcomes.
Conclusions: Our results suggest an increase in HIV virulence among UK MSM. This finding may translate to an increase in HIV incidence in the UK.

1016  HIV, Non-Communicable Chronic Diseases and Associated Factors in Tanzania and Uganda

Saied H. Kapiga1, Kathy Basile2, Samuel Biraro3, Bazil Baltazar3, Fiona Ewings3, Hashim Ramadhani3, Robert Peck4, Richard Hayes5, Paula Munderi6, Heiner Grosskurth1
1Infectious Disease Epidemiology, London School of Public Health, Mwanza, Tanzania, United Republic of; 2Infectious Disease Epidemiology, London School of Public Health, Mwanza, United Kingdom; 3MRC/Ugari Uganda Research Unit on AIDS, Entebbe, Uganda, 4Mwanza Intervention Trials Unit, Mwanza, Tanzania, United Republic of; 5Bugando Medical Centre, Mwanza, Tanzania, United Republic of; 6Infectious Disease Epidemiology, London School of Public Health, London, United Kingdom

Background: HIV remains a major public health problem in sub-Saharan Africa (SSA), alongside a growing burden of non-communicable chronic diseases (NCDs). Expanded access to antiretroviral treatment has transformed HIV to become a manageable chronic condition, further increasing the burden of these diseases. We conducted a population survey in northwestern Tanzania and southern Uganda in May 2012-April 2013 to determine the prevalence of HIV, NCDs, and associated factors. The aim of this analysis was to assess factors associated with HIV and the distribution of NCDs by HIV status.

Methodology: We used a stratified, multistage sampling design, with 5 strata in each country. We sampled 9 clusters from each stratum with probability proportional to the number of households (HHs); within each cluster we took a random sample of 10 (urban) or 15 (rural) HHs. Adults ≥ 18 years in the selected HHs were invited to participate. Consenting adults were interviewed and examined for signs of NCDs, and blood samples were collected for HIV and diabetes testing. We estimated the prevalence of HIV by county and location (urban and rural), and the prevalence of hypertension, diabetes, heart failure and chronic obstructive pulmonary disease (COPD) by HIV status. We investigated factors associated with HIV prevalence using logistic regression to estimate odds ratios (OR) and 95% confidence intervals (CI). All analyses were adjusted for the survey design.

Results: 1984 adults were enrolled. Age-adjusted HIV prevalence was slightly higher in Uganda (11.2%, CI=7.8-14.5%) than in Tanzania (10.0%, CI=5.5-14.5%). The prevalence of hypertension was 25.1% in Uganda and 16.5% in Tanzania; diabetes 3.2% in Uganda and 1.3% in Tanzania; and COPD 6.5% in Uganda and 5.0% in Tanzania. The prevalence of the NCDs did not vary by HIV status. Sociodemographic factors independently associated with HIV prevalence were increasing age, female gender, marital status (highest in those separated, divorced or widowed), and occupation group (highest in self-employed). Behavioural factors associated with HIV prevalence were current smoking and alcohol drinking (compared with non-drinking). However, there was some evidence that the effect of drinking varied by country: problem drinking was associated with an increased risk of HIV in Uganda, but not in Tanzania (p for interaction=0.09).

Conclusions: The high HIV prevalence indicates that the infection continues to be a major public health challenge in both countries. NCDs were common in both rural and urban areas, with hypertension having the highest prevalence. We found no differences in NCDs by HIV status, but may have been limited by low power. Control of emerging NCDs, alongside HIV prevention and treatment, has become a major priority in this population.

1017  Female Partner Bacterial Vaginosis and the Penis Microbiota: Rakai, Uganda

Cindy Liu1, Bruce Hungate2, Aaron Tobian3, Jacques Ravel2, Jessica Prodger2, David Serwadda4, Fred Nalugoda4, Maria Wawer6, Ronald Gray6, Lance Price7
1Department of Pathology, Johns Hopkins School of Medicine, Baltimore, MD, United States, 2Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ, United States, 3Institute for Genome Sciences, Baltimore, MD, United States, 4Department of Medicine, University of Toronto, Toronto, ON, Canada, 5Rakai Health Sciences Program, Entebbe, Uganda, 6Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, 7Translational Genomics Research Institute, Flagstaff, AZ, United States

Background: Bacterial vaginosis (BV) is a risk factor for HIV acquisition in women and is highly prevalent in African and African-American populations. BV is not currently considered a sexually transmitted infection; however, our previous work showed that male circumcision decreases female partner BV and reduces penile BV-associated bacteria in men. In the current study, we investigated the association between female partner BV status and the penile microbiota in uncircumcised men.

Methodology: We analyzed the coronal sulcus microbiota composition and density in uncircumcised men (n = 165) from Rakai, Uganda using 16S rRNA gene-based pyrosequencing and quantitative PCR, respectively. The association between host characteristics and microbiome composition was assessed using vector analysis and community state types (CSTs) were defined by hierarchal clustering. We then evaluated the association between partner BV status defined by Nugent score and coronal sulcus CSTs.

Results: Female partner BV was significantly associated with coronal sulcus microbiota composition (p = 0.04, r2 = 0.02). Although composition of the microbiota was variable, seven distinct community state types were identified (CST1-7). Based on the total amount of bacteria within the microbiota, i.e., bacterial density, the seven CSTs could be collapsed into low-density (CST1-3) and high-density (CST4-7) groups. In the high-density group, BV-associated organisms such as Prevotella, Porphyromonas, Mobiluncus, and Dialister were common and significantly more prevalent than in the low-density group. Men with high-density CSTs were more likely than men with low-density CSTs to have a female partner with BV (RR=1.55, 95% CI 1.07-2.24). In the low-density group, men whose partner had BV decreased abundance of Lactobacillus and Staphylococcus and increased abundance of Prevotella and Mobiluncus.
Conclusions: We observed frequent carriage of BV-associated organisms in uncircumcised men and demonstrated an association between partner BV and male carriage of BV-associated bacteria. This suggests that men may serve as a reservoir of BV-associated bacteria, which could lead to BV recurrence and persistence.

1018 Low Viral Suppression and High HIV Diagnosis Rate Among MSM With Syphilis - Baltimore, Maryland
Laura A. Cooley1, Marcia L. Pearl1, Colin Flynn1, David S. Blythe1, Christine Ross1, Geoffrey Hart-Cooper1, James Morgan1, Alexandra M. Oster1
1Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States, 2Maryland Department of Health and Mental Hygiene, Baltimore, MD, United States, 3Division of STD Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States, 4Baltimore County Department of Health and Human Services, Baltimore, MD, United States

Background: In 2011, Baltimore, MD, had the second highest rate of primary and secondary (P&S) syphilis and the sixth highest rate of diagnosed HIV infection among US metropolitan statistical areas. MSM are particularly affected by both infections and by coinfection; 65% of MSM with P&S syphilis in Baltimore in 2011 were infected with HIV. Viral suppression, though low nationally, can reduce HIV transmission. We determined HIV co-infection and viral suppression for MSM with single and repeat syphilis in the Baltimore area to guide prevention efforts among MSM.

Methodology: We analyzed STD and HIV surveillance data for MSM aged ≥15 years from Baltimore City or County who were diagnosed with early (primary, secondary, or early latent) syphilis infection during 2010-2011. MSM who received appropriate treatment for a previous syphilis diagnosis during 2007-2011 were defined as having repeat syphilis. We used HIV surveillance data to identify HIV coinfection and to obtain viral load results reported to the health department. For MSM diagnosed with HIV, we assessed viral suppression, defined as last viral load within the year prior to syphilis diagnosis <200 copies/mL. For MSM not diagnosed with HIV at or before their syphilis diagnosis, we used new HIV diagnoses divided by total person-years at risk (defined as days between syphilis diagnosis and the end of 2012, over 365.25) to estimate the annual HIV diagnosis rate; this analysis was limited to Baltimore City, where all new HIV diagnoses occurred.

Results: Of 460 MSM with early syphilis in 2010 or 2011, 92 (20%) had repeat infection; 26% of repeat infections occurred ≤12 months apart and only 47% were diagnosed as P&S syphilis. Fifty-five percent of Baltimore area MSM with single syphilis and 86% with repeat syphilis were HIV-infected at the time of their most recent syphilis diagnosis. Among MSM diagnosed with HIV, viral suppression was low (22% with single syphilis, 37% with repeat syphilis). For Baltimore City MSM who were not HIV-positive at the time of their syphilis diagnosis, the estimated annual HIV diagnosis rate was 4.8% (single) and 14.3% (repeat), compared with 3% for MSM overall in Baltimore City in 2011.

Conclusions: MSM with syphilis in Baltimore City have high HIV diagnosis rates. The majority of Baltimore area MSM with syphilis infection also have HIV, and consistent with national data, few appear to be virally suppressed (however, using data reported to surveillance has limitations and thus true levels of viral suppression may be underestimated). There may also be missed opportunities for early diagnosis of syphilis. Increasing the frequency of syphilis testing among MSM with a prior syphilis diagnosis and prioritizing MSM with syphilis in efforts to achieve viral suppression may improve outcomes for both infections.

1019 Trends in Comorbid Conditions Mentioned With HIV Disease On Death Certificates, US, 2000-2010
Kpandja Djawe, Kate Buchacz, Charles E. Rose, John T. Brooks
Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Epidemiology Branch, Atlanta, GA, United States

Background: HIV-infected patients are living longer due to advances in antiretroviral therapy (ART) but non-AIDS-related conditions (NARCs) in this aging population may limit survival. We explored temporal trends in AIDS-related conditions (ARCs) and NARCs recorded on death certificates along with HIV.

Methodology: Multiple causes of death data from the Centers for Disease Control and Prevention’s (CDC) WONDER, an on-line database of public data compiled and managed by CDC programs, was used to identify deaths associated with HIV (HIV deaths) in the United States among individuals, 30-49 years and 50-69 of age, that occurred between 2000 and 2010. Coefficients of association (CoA) between HIV death and select representative NARCs and ARCs were determined to explore how associations between HIV and these conditions at death evolved over time.

Results: Of the 8,108,285 deaths among individuals aged 30-69 years in the United States that occurred between 2000 and 2010, HIV was mentioned as cause among 140,172; persons aged 30-49 years and 50-69 years accounted for 91,342 (65.2%) and 48,830 (34.8%) of these deaths, respectively. The overall percentage of HIV deaths was 1.7%: 4.6% for persons aged 30-49 years and <1% for persons aged 50-69 years. Between 2000 and 2010, the overall percentage of deaths declined from 2.1% to 1.2%; for persons aged 30-49 years it declined from 6.1% to 2.7% while for persons aged 50-69 years it remained stable and <1%. The percentage of HIV deaths with a non-HIV underlying cause increased from 8% in 2000-2001 to 12% in 2008-2010 among persons aged 30-49 years, and from 18% in 2000-2001 to 26% in 2008-2010 among persons aged 50-69 years (all p<0.01). For example, among decedents aged 50-69 years, CoAs between HIV and both chronic heart disease and colon cancer increased while CoAs between HIV and both cryptococcosis and toxoplasmosis decreased during the 10-year period (Figure A-D). Among decedents aged 30-49 years, the CoA between HIV and chronic heart disease increased but CoAs between HIV and other selected conditions did not change significantly [Figure A-D].

Conclusions: As the percentage of HIV deaths in the United States has declined, especially among young adults, both the percentage of deaths with a non-AIDS underlying cause and the associations between HIV and NARCs have increased. These trends highlight a growing need for chronic disease prevention in the aging U.S. HIV-infected population.
The Association Between HPV and HIV Shedding in Vaginal and Anorectal Specimens

Julia Hood1, Geoffrey Gottlieb2, Papa Sali Sow2, Macoumba Toure2, Qinghua Feng1, Nancy Kiviat2, Stephen Hawes1

1Epidemiology, University of Washington, Seattle, WA, United States; 2Medicine, University of Washington, Seattle, WA, United States; Infectious Disease, University of Dakar, Dakar, Senegal; Pathology, University of Washington, Seattle, WA, United States; 5Epidemiology, Global Health, University of Washington, Seattle, WA, United States

Background: With growing observational evidence that HPV is associated with an increased risk of HIV acquisition, the potential of HPV vaccination as an HIV prevention strategy has been increasingly considered. However, the relationship between HPV and HIV transmission risk is unclear. In this analysis, the relationship between HPV and local HIV shedding was assessed in two diverse populations: Senegalese women and US men who have sex with men (MSM).

Methodology: Data from two longitudinal studies conducted in Senegal and Seattle with similar protocols was analyzed. The Senegal sample was comprised of 404 study visits from 169 HIV-1 infected women from whom cervical cellular and cervicovaginal fluid (CVF) specimens were collected for cytologic screening, HPV DNA detection, and HIV RNA detection and quantification. The Seattle sample was comprised of 2346 visits from 333 HIV-1 infected MSM from whom anorectal swab specimens were collected and underwent similar laboratory assessment. Multivariable generalized estimating equation regressions, controlling for age, plasma viral load, and CD4 count, were used for all analyses.

Results: In the sample of treatment-naïve Senegalese women, cervical lesions, but not HPV infection, were significantly associated with increased detection of HIV RNA (aRRlesions = 1.21, 95% CI = 1.09, 1.34) and quantity of HIV RNA in CVF (adjusted \( \beta \) lesions = 0.60 log copies/ml, 95% CI = 0.12, 1.09). In the sample of MSM, neither HPV infection nor anal lesions were associated with detection or quantity of HIV RNA in the anal canal. In MSM, subsequent analyses stratified by ART status yielded similar results.

Conclusions: The null results from two contrasting populations provide compelling evidence that HPV infection is unassociated with local HIV shedding; a finding that casts doubt on the potential of HPV vaccination to reduce the risk of HIV transmission at the population level. While it is theoretically possible that the prevention of cervical lesions through HPV vaccination could affect HIV shedding in the genital tract of HIV-positive women, the modest effect size observed in these data suggest that interventions through this causal pathway would yield minimal impact on HIV transmission at the population level. Nonetheless, the potential of HPV vaccination to prevent HIV acquisition remains unclear and might warrant further investigation.

Incidence of Sexually Transmitted Diseases Among Persons With HIV, New York City, 2000-2010
Sarah L. Braunstein1, Preeti Pathela1, Laura Kersanske1, Colin Shepard1
1Bureau of HIV/AIDS Prevention and Control, New York City Department of Health and Mental Hygiene, Queens, NY, United States, 2Bureau of STD Control, New York City Department of Health and Mental Hygiene, Queens, NY, United States

Background: Diagnoses of sexually transmitted diseases (STD) among persons with HIV (PWH) are objective markers of ongoing sexual risk behavior, and signal potential for secondary HIV transmission. Recent population-level estimates of STD incidence among PWH in New York City (NYC) are lacking.

Methodology: We conducted a retrospective cohort analysis of STD incidence among PWH using a match of the NYC HIV and STD surveillance registries. The matched dataset contained 232,295 HIV/AIDS cases reported through 3/31/2011, and 618,597 STD cases reported from 1/1/2000-6/30/2010. From the matched dataset, we constructed an analytic cohort of 42,120 PWH (≥13 years old) diagnosed with HIV during 6/1/2000-6/1/2009. Persons were followed until first incident STD (chlamydia (Ct), gonorrhea (GC), syphilis), death or end of follow-up (6/1/2010). Persons were considered at risk for incident STD only after ≥14 days from HIV diagnosis to allow opportunity for receiving their HIV test results, plus STD-specific intervals based on STD incubation periods. We calculated STD incidence overall and by demographic groups and identified predictors of incident STD in multivariable Cox regression models.

Results: Among the cohort of 42,120 PWH, 4,407 (10.5%) had an incident STD during follow-up. Among those, 33.2% were GC, 33.3% were CT, and 33.5% were syphilis. A higher proportion of persons with incident STD were male, young, white and men who have sex with men (MSM) compared to persons without incident STD. Cohort participants contributed a total of 215,536 person-years (PY) of observation (median: 4.97). Overall STD incidence was 2.0/100 PY. Median time to incident STD was 1.9 years, and 12.9% of incident STD were diagnosed ≤6 months after HIV diagnosis. Incidence rates were higher among males (2.5/100 PY versus 1.1/100 PY in females); among young persons (6.9/100 PY in persons age 13-19 versus 2.0/100 PY in persons age 30-39); among whites (2.9/100 PY versus 1.9/100 PY each in blacks and Hispanics); and among MSM (4.1/100 PY versus 1.2/100 PY in heterosexuals). Young age, black race, Hispanic ethnicity and MSM status were predictors of STD incidence among men. Among women, young age, heterosexual HIV risk and history of injection drug use were predictors of incident STD.

Conclusions: We documented substantial risk of incident STD following HIV diagnosis in the population of PWH in NYC during an eleven-year period. Incidence was elevated among certain population subgroups, including young persons and MSM. Findings underscore the need for frequent STD screening and prevention counseling for all PWH, and especially for high-risk persons, at the time of HIV diagnosis.

Increasing Rates of STI Are Linked To Reduced Condom Use in Patients With Primary HIV-1 Infection
Dominique L. Braun, Roger Kouyos, Raffael Ghentzi, Christina Grube, Rainer Weber, Hudrich Günthard
Division of Infectious Diseases and Hospital Epidemiology, University Hospital Zurich, Zurich, Switzerland

Background: In Switzerland, incidence of sexual transmitted infections (STI) is increasing in HIV positive individuals, particularly including an epidemic for sexually acquired acute HCV-infection in MSM. Patients with a primary HIV-infection (PHI) represent a sexual highly active population and may contribute to this epidemic, possibly due to changed sexual risk practices influenced by the “Swiss statement” in 2008, postulating that individuals on effective antiretroviral therapy are non-infectious.
Methodology: Between January 2002 and April 2013 we prospectively enrolled 293 individuals with a well defined PHI in the Zurich Primary HIV Infection Study and in the Swiss HIV cohort study (SHCS). At study-begin, individuals were actively screened for hepatitis C and B, syphilis, gonorrhea, chlamydia and herpes genitalis. During the study-period, STI-screening was performed based on clinical symptoms, reported sexual risk practices and by yearly serological syphilis and HCV testing. STI were determined by a detailed medical chart review including history, symptoms of STI and screening tests. Condom use is reported in the SHCS database 6 monthly. The impact of calendar year and condom use on HCV/syphilis incidence was assessed with Cox-proportional-hazard models.

Results: We analysed 293 individuals (271 males). Transmission mode included MSM (79%), heterosexual (20 %) and IVDA (1 %). Of all, 49 (17%) individuals had a concomitant STI at presentation. During follow-up period, syphilis was the most prevalent STI with 93 cases, followed by gonorrhea: 40, chlamydia: 38; acute HCV-infection: 16; herpes genitalis: 8; acute hepatitis B: 2. Incidence rates of syphilis and acute HCV-infections were significantly increasing over the study-period, most pronounced in the latter (figure 1, panel A). For syphilis, there was a significant linkage between increasing incidence and imperfect condom use (p<0.001), whereas for acute HCV-infection such correlation was also found, but only as a trend (p=0.18) (figure 1, panel B).

Conclusions: Increasing incidence rates of STI's represent a surrogate for changed sexual risk behavior in patients with PHI, may be fostered by the “Swiss statement” that has been endorsed however only for patients in stable partnerships. The ongoing epidemic of acute HCV-infections affecting MSM can not solely be explained by unprotected sex and remains unclear. Risk-group targeted prevention programs, mainly propagation of condom use, are urgently needed.

Figure 1: Panel A shows the incidence rate of syphilis and HCV during the study-period, panel B the incidence rate influenced by the factor “unprotected sex”.

1023 Does Substance Use Compromise Depression Treatment? A Randomized Trial of Homeless HIV+ Persons

David J. Grelotti1,2, Gwendolyn P. Hammer1, James W. Dilley1, Dan H. Karasic1, James L. Sorensen1, David R. Bangsberg1,4, Alexander C. Tsai1

1Department of Epidemiology, Harvard School of Public Health, Boston, MA, United States, 2Department of Psychiatry, Massachusetts General Hospital, Boston, MA, United States, 3Division of Communicable Disease Control, Communicable Disease Emergency Response Branch, California Department of Public Health, Richmond, CA, United States, 4Department of Psychiatry, University of California San Francisco, San Francisco, CA, United States, 5Department of Medicine and MGH Center for Global Health, Massachusetts General Hospital and Harvard Medical School, Boston, MA, United States, 6Ragon Institute of MGH, MIT, and Harvard, Boston, MA, United States

Background: Many clinicians will defer antidepressant treatment in the context of active substance use due to concern that active substance use will interfere with depression treatment response. Although there is evidence to the contrary, less is known about how active substance use affects depression treatment among persons with HIV. The public health impact of research in this area is particularly significant given the known adverse effects of depression on HIV-related health outcomes. We explored the effect of active substance use on depression treatment using data from a randomized clinical trial of depression treatment in HIV-infected, homeless and marginally housed persons in San Francisco.

Methodology: All participants were diagnosed with a depressive disorder and randomly assigned to either a referral to community mental health treatment (N=71) or directly observed therapy with fluoxetine (N=66). Assessments, conducted every three months over a nine-month period, included the Hamilton Rating Scale for Depression, the Beck Depression Inventory, and self-report of any alcohol, crack, cocaine, heroin, or methamphetamine use in the past 90 days. We fit multilevel mixed-effects linear regression models to estimate the effect of depression treatment on depressive symptom severity, stratified by any alcohol use or any drug use in the past 90 days.
Results: The effect of fluoxetine treatment on depression symptom severity was statistically significant irrespective of alcohol use status (see Table). When stratified by drug use status, the effect of fluoxetine treatment on depression symptom severity was statistically significant only among drug non-users. The observed treatment responses were generally smaller among alcohol and drug users than among nonusers, but the interaction terms were not statistically significant.

Conclusions: We found that antidepressant treatment reduces depression symptom severity among HIV-infected patients with depressive disorders irrespective of comorbid active substance use. Given prior work in this area, depression treatment among active substance users may also improve HIV-related health outcomes. An important limitation of this study was that our measures of substance use were self-reported and did not assess the extent to which substance use was associated with clinically significant impairment. Future studies should be powered to examine the effect of problematic substance use on antidepressant treatment response.

Session P-W9 Poster Session
Thursday March 6, 2014, 2:30 PM–4:00 PM  Exhibit Hall D
Transmission/Risk Factors

George Githuka1, Wolfgang Hladik2, Samuel Mwalili3, Davies Kimanga1, Mamo Umuro4, Mercy Muliuki2, Joshua Gitonga1, William Maina1, Andrea A. Kim2

Background: In Kenya, 5.6% of the adult population were living with HIV in 2012. Embedded in this HIV epidemic are key populations (KP) that have higher risks for HIV exposure, including persons who inject drugs (PWID), men who have sex with men (MSM), and persons who engage in transactional sex, including male sex workers (MSW), female sex workers (FSW) and male clients of FSW. Lack of national estimates of population sizes and burden of HIV among KP impedes HIV programmatic activities. We present data from the 2nd Kenya AIDS Indicator Survey (KAIS 2012), the first survey in Kenya to estimate the size of and HIV prevalence of KP on a national level.

Methodology: KAIS 2012 was a nationally representative survey of persons aged 15-64 years. Participants were interviewed and provided blood samples for centralized HIV testing. Data were weighted to account for the complex survey design and adjust for non-response. National population estimates were generated using un-normalized survey weights reflective of the 2012 projected population from the 2009 national census.

Results: Out of 5,766 men and 7,954 women, 0.1% (95% confidence interval [CI] 0.03-0.2) reported ever injecting drugs. Among men, 0.6% (CI 0.3-0.9) ever had anal sex with another man, and 0.1% (CI 0-0.2) had done so in the past 12 months. The percentage of men who engaged in MSW behavior was 3.0% (CI 2.4-3.7) and in the past 12 months was 0.8% (CI 0.5-1.1). Among women, the percentage that had ever engaged in FSW behavior was 4.5% (CI 3.8-5.2) and in the past 12 months was 1.3% (CI 1.0-1.7). Among men, 17.6% (CI 15.6-19.5) had ever been a male client of FSW, and 5.7% (CI 4.7-6.7) had reported engaging in this behavior in the past 12 months. Among male clients of FSW, 11.6% had ever engaged in MSW behavior. HIV prevalence was 0% MSM, 6.3% (CI 0.0-33.5) PWID, 6.9% (CI 4.7 - 9.1) male client of FSW, 7.3% (CI 1.7- 12.8) MSW, and 10.9% (CI 6.4 - 15.3) FSW.
Conclusions: National population sizes of KP were consistent with the 2012 national consensus estimates for KP based on regional-level data. However, HIV prevalence for MSM, MSW, and FSW were lower than those reported in other studies. These data should be considered minimum estimates as KP are less likely to be included in a household survey sampling frame and reporting bias due to stigmatization of high-risk behavior is likely. Special studies targeting KP are needed to fully understand their contribution to the HIV epidemic.

1025 HIV Incidence in Rural Western Kenya Using Longitudinal Analysis From Home-Based HIV Testing
Lisa A. Mills1, 2, George Olilo2, Manase Amolloh2, Daniel Kwaro2, Victor Ssempija1, Fredrick Odongo2, Fredrick Otieno2, Maquins Sewe2, John Williamson1, Kayla Laserson1
1Centers for Disease Control and Prevention, Prevention, Kisumu, Kenya, 2Centers for Disease Control and Prevention Research and Public Health Collaboration, Kisumu, Kenya

Background: Quantifying HIV incidence rates in affected communities is vital to epidemic characterization and response. We analyzed HIV acquisitions among repeated participants in a community-wide home-based testing and counseling (HBTC) program in rural western Kenya in which rapid scale-up of combination HIV prevention services is ongoing.

Methodology: Two rounds of community HBTC were carried out in the KEMRI/CDC Health and Demographic Surveillance Area spanning January 2010 to August 2011 [R1] and January 2012 to October 2012 [R2]. Persons ≥13 years of age found at home were asked to consent, answer questions about past testing, and undergo point-of-care rapid HIV testing using a Kenyan national algorithm. An aggregate HIV status variable was defined for each round, prioritizing HIV test results whenever available but also including self-reports. HIV+ persons previously HIV- were identified, and person-time denominators defined by time between participation in the two rounds of HBTC. Analysis was performed for participants 15-64 years of age because incidence was negligible for those <15 and ≥64 years of age.

Results: Among 33,651 participants in R1, overall HIV prevalence was 15.0% (95% Confidence Interval, CI: 14.6%, 15.5%); gender-specific prevalence was 11.6% among males (95% CI: 11.0%, 12.1%), and 17.5% among females (95% CI: 16.9%, 18.1%). Out of 8,706 individuals who participated in both rounds of testing, 124 became HIV+, resulting in an annual estimated HIV incidence rate of 1.17% (95% CI: 0.98%, 1.39%). No differences were noted between genders; however, incidence peaked among females at 25-34 years of age (1.6% ; 95% CI: 1.07%, 2.43%), and among males at age 35-44 years (2.4%; 95% CI: 1.4%, 4.2%).

Conclusions: HIV transmission continues despite programmatic scale-up of HIV prevention, care, and treatment services in this highly characterized community with traditionally low male circumcision (MC) coverage. Longitudinal incidence estimates and home-based testing campaigns have limitations, including differential nonparticipation by those most likely to be HIV infected. Cross-sectional incidence estimation, and analyses of socio-behavioral correlates of incident HIV infections for the same population should be undertaken to guide implementation of optimized HIV prevention efforts.

1026 Temporal Trends in HIV-1 Incidence and Risk Behaviors Among MSM, Bangkok, Thailand, 2006-2013
Timothy H. Holtz1, 2, Philip A. Mock1, Warunee Thienkrua1, Wannee Chonwattana1, Wipaporn Wimonsate1, Supaporn Chaikummao1, Wichuda Sukwicha1, Anupong Chitwarakorn1, Marcel E. Curlin2
1HIV/AIDS Research Program, Thailand MOPH - US CDC Collaboration, Nonthaburi, Thailand, 2Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States, 3Department of Disease Control, Thailand MOPH, Nonthaburi, Thailand

Background: We assessed temporal trends in HIV-1 incidence and behavioral risk factors from two data sources among men who have sex with men (MSM) attending the Silom Community Clinic (SCC) in Bangkok from 2006-2013.

Methodology: Incidence was calculated from: 1) a cohort of clients attending voluntary counseling and testing (VCT) services who were HIV-negative at baseline and returned for at least one additional test; and 2) MSM and transgender women aged ≥18 years participating in the Bangkok MSM Cohort Study (BMCS) who were HIV-negative at enrollment and returned for 4-month follow-up visits to a maximum of 60 months . BMCS participants provided socio-demographic and sexual risk behavior data by audio-computer-assisted self-interview. VCT HIV testing followed a three-step algorithm using rapid HIV tests on blood. BMCS HIV testing was performed on oral fluid; with serologic confirmation of all reactive specimens, and all negative specimens obtained after February 2010. Assuming uniform distribution of seroconversion between last negative and first positive test, we evaluated trends in HIV incidence per 100 Person Years (PY) by quarter using a restricted cubic spline for time in a Poisson regression, and trends in behavioral risk factors were assessed using Generalized Estimating Equations logistic regression with 95% Confidence Intervals (CI).

Results: From 2006-2013, 7263 MSM clients came to the SCC for VCT; 1779 (24%) participants were initially seronegative and voluntarily returned for another test (median testing interval 203 days). Among these individuals, we detected 192 seroconversions for an overall HIV incidence density of 5.5 PY (95% CI: 4.7-6.3). Modeling of the time trend showed a significant positive linear effect (p = 0.03). Among 1744 BMCS participants followed from 2006-2013, 1372 tested HIV-negative at baseline, and 1259 (72%) seronegative MSM at baseline repeated testing. We detected 232 seroconversions, for an overall HIV-incidence density of 5.3 PY (95% CI: 4.7-6.1). Over time HIV incidence rose, then declined (inverted U-shaped curve). Modeling of the time trend showed significant non-linear and quadratic effects (p < 0.001). Overall drug use (p = 0.045), drug use to enhance sex, use of erectile dysfunction drugs, and 100% condom use increased (all three at p < 0.001), while the proportion of MSM reporting unprotected receptive anal intercourse decreased (p = 0.04) over time.
Conclusions: Between 2006 and 2013, the incidence of HIV infection increased among MSM seen for VCT. In contrast, HIV infection among MSM in the BMCS increased from 2006 to 2008 but had an overall downward trend thereafter, possibly due to changing behavior after study enrolment. Regular testing, counseling, and education may have had a positive impact.

1027 The Potential Impact of Targeting Prevention Strategies To HIV-Discordant Households

Ruth Emerson1, Deborah Donnell1, George Bicego1, Khanya Mabuza2, Stephane Hellingringer3, Jessica Justman1
1Statistical Center for HIV/AIDS Research & Prevention, Fred Hutchinson Cancer Research Center, Seattle, WA, United States, 2Centers for Disease Control and Prevention, Atlanta, GA, United States, 3National Emergency Response Council on HIV and AIDS, Kingdom of Swaziland, Manzini, Swaziland

Background: While HIV prevention trials have identified promising interventions, it remains unclear how to maximize population-level impact and efficiency. Swaziland HIV Measurement Survey (SHIMS) data allow exploration of the potential public health gains achieved through targeting prevention to HIV-negative individuals living in HIV-discordant households.

Methodology: SHIMS estimated HIV incidence in Swaziland using prospectively observed seroconversions in a population-based longitudinal cohort. From a representative sample of 14,891 households, 18,172 adults (age 18-49) provided baseline clinical and demographic information and underwent HIV counseling and testing; 11,227 HIV-uninfected participants (6,225 women, 5,002 men) were re-tested 6 months later. Using logistic regression models, we examined whether HIV-negative individuals living in households with HIV-positive members, i.e., in HIV-discordant households, were at heightened risk of seroconversion. We compared the number needed to treat (NNT) to prevent one seroconversion per year under a hypothetical roll-out of pre-exposure prophylaxis (PrEP), applying the highest observed PrEP efficacy of 73%.

Results: Baseline HIV prevalence in 2011 was 32% (women: 38%, men: 22%). Of 6,948 households with at least one HIV-negative member followed for seroconversion, a total of 1,938 households (28%) were HIV-discordant per baseline testing. There were 148 seroconversions (101 women, 47 men), corresponding to an annualized incidence of 2.4% (women: 3.0%, men: 1.7%), and 40% of serocurrences occurred in HIV-discordant households. Having an HIV-positive household member of either sex predicted seroconversion for women (OR: 1.6, 95% CI: 1.2-2.4) and men (OR: 1.9, 95% CI: 1.1-3.5). For women, having an HIV-positive man in the household was associated with seroconversion (OR: 3.4, 95% CI: 2.1-5.6); however, for men, having an HIV-positive woman in the household was not (OR: 1.6, 95% CI: 0.9-3.2). The NNT with PrEP in order to prevent one seroconversion per year would be 37 among individuals of either sex living in HIV-discordant households, 15 among women living in households with HIV-positive men, and 51 among men living in households with HIV-positive women.

Conclusions: In Swaziland, a large fraction of seroconversions occur in HIV-discordant households. Identification of women in HIV-discordant households may allow more efficient targeting of prevention for women, while targeting prevention for men may require other approaches. Further work is needed to distinguish whether the observed association between household HIV-discordancy and seroconversion is due to within-household transmission or shared household risk factors.

1028 The Effect of Sexually Transmitted Infections On HIV Incidence Among MSM in Atlanta, GA

Colleen F. Kelley, Adam S. Vaughan, Nicole Luisi, Travis Sanchez, Paula Frew, Carlos del Rio, Patrick S. Sullivan, Eli S. Rosenberg
Center for AIDS Research, Emory University, Atlanta, GA, United States

Background: Sexually transmitted infections (STI) have long been associated with HIV acquisition. However, controlling for behaviors that confound the examination of a causal relationship is difficult. Also, data examining the relationship between STI and HIV acquisition among men who have sex with men (MSM) in the southeastern US are lacking.

Methodology: The InvolveMENt study is an ongoing, longitudinal cohort of black and white HIV-negative, sexually active MSM aged 18-39 in Atlanta. MSM were recruited from community venues and the internet, screened routinely at 3-6 month intervals for urethral and rectal N. gonorrhoeae (GC) and C. trachomatis (CT) by NAAT, syphilis by RPR/Treponemal IgG, HIV with rapid antibody tests, and completed questionnaires. MSM were linked to care for treatment of new STI and HIV. To address the dual and potentially conflicting needs for confounding control and statistical efficiency in estimating effects of STI on HIV incidence, we used propensity-score weighted cox proportional hazards models. Weights represented the inverse probability of incident STI diagnosis from logistic regression models of STI diagnosis as a function of age, race, time, time-dependent number of unprotected anal intercourse partners, report of receptive anal intercourse, poverty, and drug use.

Results: We included 512 HIV-negative MSM with 743 person-years of follow-up in this analysis. Over the study course, 20 syphilis, 27 urethral CT, 8 urethral GC, 45 rectal CT, 38 rectal GC, and 23 HIV incident cases were diagnosed. Overall, ≥90% of STI were treated. No MSM with urethral STI or syphilis acquired HIV during study follow-up. Only having a rectal STI (GC and/or CT) was significantly associated with subsequent HIV incidence in unadjusted analyses (HR 5.2, 95% CI 1.8,15.2). Adjustment with modeled weights refined the rectal STI association (aHR 4.0; 95% CI 1.9, 8.5), using weights from a rectal STI propensity model that substantially controlled confounding (c-statistic = 0.79). Analyses limited to rectal CT alone or rectal GC alone gave similar estimates.

Conclusions: Among MSM in Atlanta undergoing routine STI screening and referral for treatment, only incident rectal STI was associated with HIV acquisition after controlling for known confounders. This suggests a causal effect of rectal STI on HIV acquisition among MSM even in the setting of aggressive case finding and treatment. This effect may be related to rectal mucosal changes after STI. Our data underline the importance of routine screening for STI, including rectal STI, among sexually active MSM and support targeting of intensive HIV prevention interventions for MSM diagnosed with rectal STI. Further studies of the effect of STI on the rectal mucosa are needed to better understand HIV transmission in MSM.
Factors Associated With HIV Discordance Among Couples in Kenya: Results From a Population Survey

Wanjiru Waruiru1, Agneta Mtithi2, Anthony Waruiru2, Jennifer Galbraith3, Timothy A. Kellogg1, Scott Epperson4, Anne Ng’ang’a4, Sophie Mwayumba5, Lucy Kimondo6, Andrea A. Kim7

1University of California, San Francisco, Nairobi, Kenya; 2National AIDS and STI Control Programme, Nairobi, Kenya; 3Centers for Disease Control and Prevention, Nairobi, Kenya; 4Centers for Disease Control and Prevention, Atlanta, GA, United States; 5National Public Health Laboratory Services, Nairobi, Kenya; 6National Council for Population and Development, Nairobi, Kenya

**Background:** The majority of HIV-1 infections in Africa occur among individuals in stable partnerships. Improving our understanding on the correlates of discordance will provide information on the dynamics and risk factors of couple transmission that can assist in the development of interventions to reduce transmission within couple relationships.

**Methodology:** The Kenya AIDS Indicator Survey (KAIS) 2012 was a population-based survey among persons aged 18 months to 64 years that collected interview data on demographics and behaviour; and a blood sample from participants for HIV testing. We analyzed data from married/cohabitating couples where HIV test results were available for both partners. We used logistic regression to identify factors associated with HIV discordance. Variables that were statistically significant at 0.10 p-value level in bivariate analyses were selected for the final multivariable model. Analyses were weighted to account for the sampling design and adjusted for non-response. Population estimates of HIV discordant couples were computed using un-normalized survey weights.

**Results:** There were 4,226 married or cohabiting couples of whom, 2,032 (48.1%) completed interviews and had HIV test results. Of all couples tested, 92.0% (95% CI 90.3-93.7; n=1,870) were HIV- concordant, 3.2% (95% CI 2.2-4.1; n=65) were HIV+ concordant and 4.8% (95% CI 3.6-6.1; n=97) were HIV discordant; translating to 260,000 discordant couples. Testing rates among discordant couples were high; 97.4% (95% CI 94.7-100.0) of women and 80.0% (95% CI 70.4-89.6) of men whose partners were HIV+ reported ever having been tested. Among all discordant couples 24.2% (95% CI 13.4-35.0) of the HIV- partners were on antiretroviral therapy (ART). Of the individuals within a discordant couple who knew they were HIV+, 64.1% (95% CI 19.9-51.8; N=36) were on ART. In the final model, factors associated with HIV-discordance were an increasing number of lifetime sexual partners in women (adjusted odds ratio [AOR] 1.3, 95% CI 1.1-1.5; p=0.001); and for men, lack of male circumcision (AOR 4.4, 95% CI 2.4-7.9; p<0.001) and reporting sexual partners outside of the relationship in the past 12 months (AOR 2.1, 95% CI 1.2-3.7; p=0.006).

**Conclusions:** These findings underscore the importance of couple-based prevention strategies that focus on reducing sexual transmission among HIV-1 infected couples including voluntary medical male circumcision, reduction of number of sexual partners, routine couples HIV counselling and testing and knowledge and disclosure of partner status. Furthermore, given the effect of antiretroviral therapy on viral load suppression, interventions that increase access and adherence to treatment can contribute to reduction in HIV transmission among discordant couples.

Partners of Individuals With Acute HIV Infection Have a High Frequency of Known HIV Infection

Philip J. Peters6, Emily Westheimer2, Stephanie Cohen3, Charles E. Rose1, Cynthia L. Gay4, Charles Fann3, Steve Beagle4,5, Kate Washburn2, Tonyka L. Jackson1,6, Lisa B. Hightow-Weidman6

1Centers for Disease Control and Prevention, Atlanta, GA, United States; 2New York City Department of Health & Mental Hygiene, New York City, NY, United States; 3San Francisco Department of Public Health, San Francisco, CA, United States; 4University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 5North Carolina Department of Health and Human Services, Raleigh, NC, United States; 6ICF International, Atlanta, GA, United States

**Background:** We evaluated if partners named by people with acute HIV infection (AHI) were more likely to be HIV-infected than those named by people with established HIV infection.

**Methodology:** The STOP study is an on-going prospective study evaluating AHI diagnosis linked to partner services at 12 HIV testing sites in New York City (NYC), North Carolina (NC), and San Francisco. Individuals newly diagnosed with either acute or established HIV infection were offered partner notification services. Contact information was elicited for sex partners from the previous three months for participants with AHI and the previous 12 months for participants with established HIV infection.

**Results:** From September 2011 to May 2013, partner services were offered to 110 individuals with AHI and 579 individuals with established HIV infection. Partner notification was accepted (i.e., provided contact information for at least one sex partner) by 82% (96/117) of individuals with newly diagnosed HIV infection in NC, 62% (192/312) in NYC (p<0.0001 vs. NC), and 30% (78/260) in San Francisco (p<0.0001 vs. other two sites). Among the 366 participants who accepted partner notification, the majority were young (59% were 17 - 29 years of age) men (94%) who have sex with men (90%). Forty-six percent reported meeting sex partners online and 38% reported having five or more sex partners. Overall, the 366 participants named 803 sex partners, of whom 32% (n=259) had been previously diagnosed with HIV infection; 38% (n=304) accepted an HIV test and 41 partners (13.5% of tested, 5.1% of all partners) were newly diagnosed with HIV infection. A comparison of partner services investigation outcomes (n=366) for participants with AHI and with established HIV infection did not demonstrate significant differences in the proportion with at least one partner: (i) with known HIV infection (59% for AHI vs. 58% for established HIV infection), (ii) with newly diagnosed HIV (12% vs. 11%), and (iii) who tested HIV negative (47% vs. 45%) [Table]. Among investigations with more than one partner, 39% (73/188) had both HIV-infected and HIV-negative partners.

**Conclusions:** In addition to diagnosing new HIV infections, notification services identified partners with known HIV infection in a similar high proportion (58%) of participants with newly diagnosed acute or established HIV infection. Ensuring that these HIV-infected partners are linked to care and treatment may be an important intervention to interrupt further HIV transmission.
Baseline Predictors of HIV-1 Acquisition Among Women Participating in MTN-003 (VOICE)

Gonasagrie Nair1, Jennifer E. Balkus2, Jeanne M. Marrazzo3, Gita Ramjee4, Baningi Mkhize5, Clemensia Nakabiito7, Marthinette Taljaard8, Kailazarid Gomez9, Zvavahera M. Chirenje10

1CAPRISA/DDRMI, Nelson R Mandela School of Medicine, Durban, South Africa, 2Fred Hutchinson Cancer Research Center, Seattle, WA, United States, 3University of Washington, Seattle, WA, United States, 4South African Medical Research Council, Durban, South Africa, 5University of Witswatersrand, Johannesburg, South Africa, 6Chris Hani Baragwanath Hospital, Johannesburg, South Africa, 7Makerere University, Kampala, Uganda, 8The Aurum Institute, Klerksdorp, South Africa, 9FHI360, Durham, NC, United States, 10UZ-UCSF, Harare, Zimbabwe

Background: In the Microbicide Trials Network (MTN) Study 003 (VOICE), the overall HIV-1 incidence was higher than anticipated, with incidence as high as 10% at some sites, despite the provision of comprehensive HIV-1 risk reduction services and condoms. Improving our understanding of predictors of HIV-1 acquisition in women is urgently needed to identify populations at greatest risk and to inform the scale-up of targeted HIV-1 prevention activities.

Methodology: MTN-003 was a randomized, double-blinded, placebo-controlled trial conducted in South Africa, Uganda and Zimbabwe between 2009-2012 that assessed the safety and effectiveness of daily oral tenofovir, oral tenofovir-emtricitabine, and 1% vaginal tenofovir gel for HIV-1 prevention. Baseline demographic, behavioral and laboratory data were analyzed from enrolled participants. Univariate and multivariable stepwise Cox proportional hazards models stratified by study site were used to assess baseline predictors of HIV-1 seroconversion.

Results: Among 5,029 women enrolled in MTN-003, 22 were determined to be HIV-1-seropositive at enrollment, 38 failed to return for follow-up, and 135 were missing baseline data, leaving 4,834 women for inclusion in the analysis; of these, 305 acquired HIV-1. The overall HIV-1 incidence was 5.68% (305/5,370 person-years). Over 20 predictors were evaluated and HIV-1 incidence (per 100 person-years), hazard ratios (HR) and 95% confidence intervals (CI) for significant predictors of HIV-1 acquisition are presented in the table.

Conclusions: Among women enrolled in MTN-003, young age and being unmarried/not living with a partner were the strongest risk factors for HIV-1 acquisition. Several other factors including not knowing if partner has other partners, having a curable STI at baseline (a biologic marker for unprotected sex), HSV-2 positive status, and alcohol use were also risk factors for HIV-1 infection. Programs and interventions that target women with these characteristics may optimize HIV-1 prevention efforts.

#### 1032 Measuring Purposefully Adopted Seroadaptive Behaviors vs Reported Sexual Behaviors Among MSM

Christine M. Khosropour1, Julia C. Dombrowski2 3, James P. Hughes1, Lisa E. Manhart1, Jane M. Simoni5, Matthew R. Golden2 3

1Epidemiology, University of Washington, Seattle, WA, United States, 2Medicine, University of Washington, Seattle, WA, United States, 3Public Health - Seattle & King County, Seattle, WA, United States, 4Biostatistics, University of Washington, Seattle, WA, United States, 5Psychology, University of Washington, Seattle, WA, United States

**Background:** Seroadaptive behaviors are common among men who have sex with men (MSM) and may protect against HIV. Most studies define seroadaptive behaviors based on men’s self-reported sexual behavior history, regardless of whether those behaviors reflect purposefully adopted risk mitigation strategies. This may not accurately define the population engaging in seroadaptive behaviors and could affect the ability to detect their potential protective effect.

**Methodology:** Among MSM attending an STD clinic in Seattle, WA from February-August 2013, we used two methods to estimate the prevalence of seroadaptive behaviors: (1) a 12-month sexual behavior history reported in a clinical computer-assisted self-interview (CASI); and (2) a research CASI which asked if subjects purposefully adopted risk reduction behaviors in the past 12 months based on partners’ perceived HIV status. We examined 3 behaviors (defined as follows for sexual behavior history vs. purposeful adoption): serosorting (only partners with concordant HIV status vs. choice of partners was based on partner’s status); condom serosorting (condom use with discordant/unknown but not with concordant status partners vs. choice to use/ not use condoms was based on partner’s status); and strategic positioning (insertive partner is HIV-negative and receptive partner is HIV-positive/unknown vs. choice to adopt an insertive or receptive role was based on partner’s status). For each behavior we compared the prevalence (McNemar’s chi-square for paired data) and agreement (kappa) between the two methods of estimation, stratified by HIV status.

**Results:** Of 1902 eligible MSM, 964 (51%) completed both CASI’s. The mean age of participants was 34 (SD=11) and 835 (87%) were HIV-negative. The prevalence of behaviors was similar for the two methods of estimation, but the agreement was low (Table). Among 388 MSM classified as serosorters per their sexual behavior history, only 175 (50.4%) of 347 HIV-negative and 29 (70.7%) of 41 HIV-positive men reported purposefully choosing not to have sex with HIV discordant/unknown status partners.

**Conclusions:** Serosorting is overwhelmingly the most common seroadaptive behavior in our clinic. The prevalence of seroadaptive behaviors varies only slightly depending on the method of estimation, but using men’s sexual behavior history likely includes men who did not purposefully adopt these behaviors. This misclassification may alter the estimated effect of seroadaptive behaviors on HIV risk.

**Prevalence and Predictors of HIV Disclosure Among Adults Receiving Care in the United States**

Christine L. Mattson1, Mark S. Freedman1, Linda Beer1, Patrick Sullivan2, Jacek Skarbinski1

1Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States, 2Emory University, Atlanta, GA, United States

**Background:** Disclosing one’s HIV-positive status to sex partners is important for preventing HIV transmission as it allows partners to make informed decisions about how to reduce their risk. However, there are no nationally representative estimates of disclosure in the United States (U.S.). We present estimates of the number and proportion of HIV-infected adults in care who disclosed their status to all sex partners in the past 12 months, along with factors associated with disclosure.

**Methodology:** We used interview and medical record data from the Medical Monitoring Project, which collects information from a probability sample of HIV-infected adults receiving medical care in the U.S. Participants were considered to have disclosed if they reported discussing their HIV-positive status with all sex partners in the past 12 months the first time they had sex with each partner. This analysis was limited to persons diagnosed with HIV for ≥1 year. We evaluated factors associated with disclosure using logistic regression analyses to calculate crude and adjusted prevalence ratios. All analyses accounted for clustering, unequal selection probabilities, and non-response.

**Results:** Among an estimated 222,648 sexually-active HIV-infected adults in care in the U.S., 178,603 or 72% (95% Confidence Interval (CI) 70%-74%) disclosed their HIV status to all partners. In adjusted analyses, men who had sex with men, Blacks/African Americans, Latinos, people who experienced homelessness, alcohol and drug users, and people who reported any unprotected vaginal or anal sex were less likely to disclose their status to all sex partners in the past 12 months (Table 1). Current use of antiretroviral therapy and viral suppression were not associated with disclosure.

**Conclusions:** Although the majority of sexually-active HIV-infected adults in care in the U.S. disclosed their status to all sexual partners in the past year, over 1 out of 4 (an estimated 69,380) did not. Disclosure was less likely among those who engaged in behaviors that increase the risk of HIV transmission (i.e., substance use and unprotected sex), highlighting the need for increased prevention efforts to encourage disclosure and receipt of risk reduction counseling among these populations.

**Trends in HIV Diagnoses Among Persons Who Inject Drugs – United States, 2008-2011**

Andrew J. Mitsch1, H. I. Hall1, Amy L. Lansky1, Aruna Surendera-Babu2

1National Center for HIV, STD, Tuberculosis, and Viral Hepatitis Prevention, U.S. Centers for Disease Control and Prevention, Atlanta, GA, United States, 2Macro International, Inc., Atlanta, GA, United States

**Background:** Injection and sexual behavior among persons who inject drugs (PWIDs) contribute importantly to the HIV burden in the United States (U.S.). In 1983, the U.S. Centers for Disease Control issued HIV prevention guidelines for PWID and others at high risk of becoming infected and transmitting infection to others. We aimed to inform how to focus prevention strategies by showing burden, trends, and geographic variations in HIV infection among PWIDs.

**Methodology:** In addition to the number of HIV diagnoses among PWIDs, we calculated diagnosis and prevalence rates for 2008 through 2011 using HIV case surveillance data and estimates of the number of U.S. residents with a history, as given in meta-analysis of national survey data, of ever having injected drugs illegally. Trends are described with estimated annual percentage change in the number of diagnoses, and stratified by sex and race/ethnicity. Further, we describe the geographic variations in HIV burden as given by counts of diagnoses among PWIDs and persons whose infections were attributable to sex with PWIDs.
1035 An Emerging HIV Epidemic Among Injection Drug User Networks During Austerity in Athens, Greece
Ashley Tsang1, John Schneider2, Vana Sypsa2, Georgios Nikolopoulos3, Dimitrios Paraskevis4, Samuel Friedman5, Angelos Hatzakis6
1University of Chicago, Chicago, IL, United States, 2Department of Medicine, University of Chicago, Chicago, IL, United States, 3National Retrovirus Reference Center, Athens, Greece, 4Heilinic Center for Disease Control and Prevention, Athens, Greece, 5National Development and Research Institutes, New York, NY, United States

Background: There is growing consensus on the role that social risk environments play in perpetuating HIV risk and transmission. Network analysis provides one method of examining the social risk environment. Networks may function as vectors of disease transmission (risk networks) or as mediums for social influence (social networks). Previous studies have described the importance of risk and social networks to HIV transmission and prevalence, but few analyses examine both network functions within the same context and population. Further, we explore these network functions within a unique context of an emerging HIV epidemic in Athens, Greece.

Methodology: We used the network generated by a respondent driven sampling referral-recruitment structure within a large HIV screening and linkage to care program among injecting drug users in Athens, Greece in 2012. For each of the 1,404 respondents, we created first, second and third degree networks. Network proportions, the proportion of a respondent’s network with a given characteristic, were calculated. Several logistic regression models were developed to assess the relationship between these network proportions and individual HIV seroprevalence, injection frequency and unprotected sex.

Results: A total of 1030 first-degree networks were generated with a network size ranging from 2 to 5. Respondent HIV seroprevalence was associated with greater proportions of network members that were HIV infected (AOR = 3.11, 95% CI: 2.10 to 4.62), were formerly incarcerated (AOR = 2.82, 95% CI: 1.48-5.37), divided drugs (AOR = 1.60, 95% CI: 1.10 to 2.3), were high frequency injectors (AOR = 1.50, 95% CI: 1.02 to 2.21) or shared injection equipment (AOR = 2.44, 95% CI: 1.10 to 5.38). High frequency injecting was associated with having more network members that were HIV infected (AOR = 1.61, 95% CI: 1.14 to 2.28), high frequency injectors (AOR = 1.66, 95% CI: 1.23 to 2.26), and homeless (AOR = 1.45, 95% CI: 1.03 to 1.93). Unprotected sex was associated with having more network members that were drug partners (AOR = 1.81, 95% CI: 1.03 to 3.17), and engaged in unprotected sex (AOR = 1.66, 95% CI: 1.03 to 2.67). Associations diminished when these models were run for more distal second and third degree networks.

Conclusions: Our analyses show that networks are an independently important contributor to the HIV outbreak in Athens Greece. These effects were strongest for the immediate network, but residual effects were seen moving out to second and third degree network members. Our results suggest that future public policies and programs should consider network-level interventions in addition to those that work at the individual level.

1036 High HIV Prevalence Among Injection Drug Users in India: Women Bear a Disproportionate Burden
Gregory M. Lucas1, Sunil S. Solomon1,2, Ayur K. Srikrishnan1,2, Syed H. Iqbal2, Oliver Laeyendecker1,3, Allison McFall1, Muniratnam S. Kumar4, David D. Celentano5, Sunil Solomon1, Shrutl H. Mehta6
1Johns Hopkins University School of Medicine, Baltimore, MD, United States, 2YR Gaitonde Centre for AIDS Research and Education, Chennai, India, 3National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, United States, 4Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

Background: While several low- and middle-income countries (including most in sub-Saharan Africa) have demonstrated >25% declines in HIV prevalence over the past decade, the burden of HIV often remains high in vulnerable subgroups, including injection drug users (IDUs). In India there has been a 50% overall decline in HIV prevalence between 2001 and 2009, however, limited data available suggest that HIV prevalence remains high in IDUs. Additionally, rates of IDU have increased sharply in some regions in North and Central India, and less is known about HIV among IDUs in these areas than in regions where IDU is endemic.

Methodology: We used respondent driven sampling (RDS) to recruit IDUs across 15 cities in India (target = 1000 per site). Participants had to be ≥18 years and report history of injection drug use in the prior 2 years. All participants underwent a survey and provided a blood sample. HIV infection was diagnosed using double ELISA and HIV prevalence was estimated incorporating RDS weights. Multi-level logistic regression was used to identify correlates of prevalent HIV infection. HIV incidence was estimated using a multi-assay algorithm incorporating HIV BED, avidity, CD4+ count and HIV RNA.
Background: In some countries, exchange sex - sex in exchange for money or drugs - plays a key role in HIV transmission due to the high prevalence of HIV among women who exchange sex and the high percentage of men who pay for sex. There is limited information in the United States about exchange sex and the association with HIV prevalence among injection drug users. We used 2009 data on female injection drug users (IDUs) from the National HIV Behavioral Surveillance System (NHBS) to estimate the percentage who exchanged sex in the past 12 months, compare HIV testing and HIV risk behaviors among women who exchanged sex and those who did not, and investigate factors associated with being HIV-positive but unaware of one’s infection.

Methodology: We analyzed data from female IDUs, aged ≥18 years, recruited using respondent-driven sampling, interviewed and tested for HIV. Women testing positive who did not report a prior positive HIV test were considered to be unaware of their infection. Using chi-square tests, we assessed differences in HIV risk behaviors, HIV testing, HIV prevalence and the percentage HIV-positive but unaware of their infection among women who did and did not exchange sex in the past 12 months. To evaluate the association between engaging in exchange sex and being HIV-positive but unaware, we used generalized estimating equations, clustered on recruitment chain, controlling for race/ethnicity, employment, total number of partners and unprotected sex in the past 12 months.

Results: Among 2784 women, 903 (32%) reported any exchange sex in the past 12 months. Unprotected sex was more common among women who exchanged sex than among those who did not (88% compared to 65%, p<0.001), as was sharing of injection equipment (56% compared to 30%, p<0.001). There was no difference in HIV testing in the past 12 months between women who exchanged sex and those who did not (55% compared to 51%, p=0.13) and no difference in HIV prevalence (10.0% compared to 8.7%, p=0.26). The percentage HIV-positive but unaware was 5.2% among those who exchanged sex and 3.4% among those who did not (p=0.02). In multivariable analysis, exchange sex was associated with being HIV-positive but unaware (adjusted prevalence ratio 1.76, 95% confidence interval 1.21-2.55).

Conclusions: Exchange sex was common among female IDUs in NHBS. Women who exchanged sex were more likely to be HIV-positive but unaware of their infection after adjusting for important covariates. HIV prevention efforts may benefit from strengthening interventions among female IDUs who exchange sex. These efforts could include reducing unprotected sex, increasing safe injection practices, and HIV testing with prompt linkage to care and treatment for those testing positive.

1037 HIV Prevalence Among Women Who Inject Drugs and Exchange Sex for Money or Drugs: 20 US Cities, 2009
Lina M. C. Nerlander, Kristen L. Hess, Dita Broz, Birn C. Le, Caitlinn Sionean, Charles E. Rose, Gabriela Paz-Bailey, for the NHBS Group
Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, GA, United States

Methodology: We analyzed data from female IDUs, aged ≥18 years, recruited using respondent-driven sampling, interviewed and tested for HIV.
women, who were prescribed EDM and the independent association between EDM prescription and unprotected intercourse (UI) using multivariate logistic regression. EDM prescription was defined as documentation of sildenafil, vardenafil, or tadalfil in the medical record in the 12 months prior to interview. UI was defined as at least one episode of anal or vaginal sex without a condom during the 12 months prior to interview. All analyses accounted for clustering, unequal selection probabilities and non-response.

Results: Among an estimated 136,320 sexually active HIV-infected MSM in care in the United States, 13% (95% Confidence Interval (CI) 10%-15%) received an EDM prescription and 56% (95% CI 50%-61%) had unprotected intercourse. MSM prescribed EDM were more likely to be aged 40 years or older, white or Hispanic, with college or higher education, above poverty level, insured, diagnosed with HIV for at least 5 years, having more than 5 sex partners, and those who used illicit drugs before or during sex. MSM prescribed EDM were significantly more likely (Prevalence Ratio 1.2; 95% CI 1.1-1.4) to have unprotected intercourse, while controlling for identified risk factors including race and ethnicity, total number of partners, depression, and illicit drug use before or during sex. Only 40% of MSM prescribed EDM had received counseling from their healthcare provider in the past 12 months on ways to protect themselves or partners from HIV or other STIs.

Conclusions: HIV-infected sexually active MSM prescribed EDM were significantly more likely to have unprotected intercourse after adjusting for other independent predictors. Despite having been prescribed EDM by their HIV provider, only 40% of MSM received risk reduction counseling. HIV providers should be aware of the potential for increased HIV transmission risk associated with prescribed EDM use.

1039 A Novel Analytical Approach Confirms Stabilization of HIV Epidemic in Pregnant Women in Namibia

Anna Jonas1, Steven Gutreuter1, Sadhna V. Patel1, Andrew Maher1, Michael de Klerk1, Tulip Nakanyala1, Francina Kaimdeo-Tijtuka1, Ella Shiheto2, David W. Lowrance3

1Ministry of Health and Social Services, Windhoek, Namibia, 2US Centers for Disease Control and Prevention, Atlanta, GA, United States, 3US Centers for Disease Control and Prevention, Windhoek, Namibia

Background: In most African countries with generalized epidemics, HIV prevalence trends are monitored primarily through antenatal care (ANC) based HIV sentinel surveillance (HSS). Reliable national and sub-national estimates of trends in HIV prevalence are needed; however, standard methods of analysis do not properly address potential biases from differences among sites and addition of sites over time. We report a novel, statistically principled estimate of trend in HIV prevalence among pregnant women from HSS from 2002 to 2012 in Namibia using Bayesian hierarchical logistic models.

Methodology: HSS data from 35 sites representing all Namibian health districts from 2002-2012 were analyzed. Two Bayesian models, hierarchical linear and state space autoregressive, were used to quantify site specific and national trends in HIV prevalence among women within 15-49, 15-19, 20-24, 25-29, 30-34, and 35-49 year age groups. Within age groups, the two Bayesian models were compared by deviance information criterion (DIC). The model which produced smaller DIC value was selected for its superior predictive ability within the age group. National trends were quantified by the linear logistic slope (b) or autoregressive (ar) parameters from the respective models, and by the probability of decreasing prevalence, Pr(↓), as measured by Pr(b<0) or Pr(ar<1), respectively. 1-Pr(↓) was used to quantify the probability of increasing prevalence. Unchanging prevalence is indicated by b=0 or ar=1 for the linear-logistic and autoregressive models, respectively. Pr(↓) ≥0.80 and Pr(↓) ≥0.99 were chosen thresholds for highly probable or nearly certain decrease/increase, respectively.

Results: From 2002-2012, HIV prevalence remained stable among women aged 15-49 (ar =0.96, Pr(↓)=0.78). A decline in prevalence was nearly certain among women aged 15-19 (b = -0.07, Pr(↓)>0.99) and 20-24 (b= -0.09, Pr(↓)>0.99), and highly probable among women aged 25-29 (ar =0.92, Pr(↓) = 0.93). An increase in prevalence was nearly certain among women aged 30-34 (b = 0.02, 1-Pr(↓) = 0.99) and 35-49 (b = 0.05, 1-Pr(↓) >0.99).

Conclusions: Overall, the trend analysis does not show strong evidence of a change in HIV prevalence, indicating epidemic stabilization since 2002. Among women aged 15-19 and 20-24, prevalence appears to have decreased, by approximately 7.0% and 9.0%, respectively, which likely indicates decreasing incidence among younger women. Among women aged 30-34 and 35-49, prevalence appears to have increased, which may indicate decreasing mortality and improved health outcomes due to ART and PMTCT scale-up, and continued occurrence of new infections among older women. The novel analytic method presented here can be adapted by other countries to produce reliable HIV prevalence trends estimates.

1040 Viral Load Strategy: Impact On Risk Behavior and Serocommunication of MSM in Specialized Care

Elisabeth Kuhn1, Anja Potthoff1,2, Henrike Dirks1, Michael Wolter1, Stefan Esser1, Norbert Scherbaum1,2, Norbert H. Brockmeyer1,2

The novel analytic method presented here can be adapted by other countries to produce reliable HIV prevalence trends estimates.
general (p = .043) and less frequent disclosing to sex partners (p = .023) were found, especially in anonymous settings. Differentiating serocommunication characteristics, a focus on seroguessing was depicted.

**Conclusions:** The user group of VLS is small, but it diverges greatly from the targeted group of VLS, which requires an informed and monogamous relationship. A less frequent, more reactive and assumptive serocommunication leads to an imprecise information exchange, paired with a higher frequency of risky behavior, especially in anonymous settings. Without an open serocommunication in these settings, other - potentially asymptomatic - STI may be passed on. Thus, a subversion of a basic condition of the VLS seems possible and the HIV transmission risk may be much higher than assumed.

**1041 Transmission Rates and Not Sexual Contact Patterns Drive HIV Epidemic Intensity in Africa**

**Steve E. Bellan**, Jonathan Dushoff, David Champredon, Alison P. Gahani, Lauren A. Meyers

1 Center for Computational Biology and Bioinformatics, University of Texas at Austin, Austin, TX, United States, 2 Biology, McMaster University, Hamilton, ON, Canada, 3 Department of Mathematics and Statistics, McMaster University, Hamilton, ON, Canada, 4 School of Medicine, Yale University, New Haven, CT, United States, 5 Integrative Biology, University of Texas at Austin, Austin, TX, United States

**Background:** HIV prevalence has peaked at less than 1% in some African countries while surpassing 30% in others. After decades of research it remains widely debated whether this variation is driven by variation in biological factors influencing the HIV transmission rate (e.g. male circumcision, coinfections, and viral or host genetics) or by variation in sexual contact patterns (concurrency, promiscuity, and age-mixing). The serodiscordant proportion (SDP; proportion of couples with any seropositive partners that are serodiscordant) also varies geographically, ranging from 38-92% across Africa, and exhibits a negative correlation with prevalence. We identify which processes shape the observed variation in both prevalence and SDP and the relationship between the two.

**Methodology:** First, we fit an HIV transmission model Demographic and Health Survey data from 45,041 cohabiting

**country (serodiscordant proportion as %)**

- DRC (91%)
- Gabon (81%)
- Congo (81%)
- West Africa (79%)
- Tanzania (72%)
- Mozambique (69%)
- Malawi (64%)
- Uganda (63%)
- Ethiopia (62%)
- Kenya (62%)
- Zambia (60%)
- Lesotho (51%)
- Zimbabwe (49%)
- Rwanda (49%)
- Burundi (47%)
- Swaziland (39%)

**P = 0.0049**
couples in 25 African countries to estimate country-specific transmission rates and sexual contact patterns. Second, we quantify the sensitivity of SDP to the HIV transmission rate, sexual contact patterns, and AIDS mortality. Third, to identify drivers of country-to-country variation in SDP, we inserted country-specific HIV prevalence, transmission rates, or sexual contact patterns estimated from a “donor” country into a model fit to a “recipient” country, and measured the extent to which the substitution shifted the SDP from that of the recipient toward that of the donor. Finally, we used generalized linear models to estimate the contribution of these factors to country-to-country variation in HIV prevalence.

**Results:** The SDP is primarily determined by the HIV transmission rate. Thus, greater HIV transmission rates explain both why certain countries have greater HIV prevalence (49% of variance explained; Figure) as well as smaller SDPs (89% explained). In contrast, sexual contact patterns explained less than 3% of variation in SDP and were not statistically significant predictors of prevalence (P > .01).

**Conclusions:** By exploring variation in HIV prevalence through the lens of serodiscordance patterns, we provide a novel and testable empirical framework to compare the two leading hypothesized drivers of variation HIV epidemic intensity. We find that, while risky sexual contact patterns cause a large proportion of HIV incidence in all countries examined, greater intrinsic transmission rates—and not riskier sexual contact patterns—explain why certain countries have suffered worse epidemic

**HIV Testing in Low Income Settings**

**1042 Community-Based Integrated Family Planning and HIV Testing and Counseling Services in Uganda**

Aurelie Brunie1, Patricia Wamala-Mucher2, Jane Harriet Namwebya1, Tricia Petruney1, **Vincent J. Wong**1, Benson Tumwesigye1, Sarah Mercer1, Victor Draman Afayo1, Angela Akol1

1FHI 360, Washington, DC, United States, 2Clinton Health Access Initiative, Kampala, Uganda, 3FHI 360, Kampala, Uganda, 4FHI 360, Durham, NC, United States, 5Office of HIV/AIDS, USAID, 1200 Pennsylvania Ave, DC, United States, 6National HTC Coordinator, Ugandan Ministry of Health, Kampala, Uganda

**Background:** In Uganda, HIV prevalence is rising and testing rates remain low. This study evaluates the safety, acceptability, and effectiveness of integrating HIV Testing and Counseling (HTC) into family planning (FP) services provided by community health workers, or Village Health Team members (VHTMs). Task-shifting combined with service integration leverages the relationship between VHTMs and communities to increase HTC uptake and meet reproductive health needs.

**Methodology:** We used a two-arm post-test only randomized cluster design in two districts. We randomly allocated eight health centers from matched pairs to intervention or control. We trained 36 VHTMs from the intervention group in HTC and adapted mechanisms for FP supervision, commodity management, and record keeping to support HTC. Proficiency testing was conducted as external quality assurance (EQA). A survey of all trained VHTMs, a survey of 256 FP clients in the intervention and control groups, and a review of record data were conducted after 10 months in Spring 2013. We calculated a composite quality score from VHTMs’ responses to questions on essential aspects of HTC. Analyses of client survey data using linear mixed models are comparing HIV testing attitudes and practices between the intervention and control groups. Client experiences with HTC services are examined descriptively.

**Results:** Record data for June–December 2012 show that VHTMs offered counseling during 1449 client visits, and tested clients in 1012 of these. More men than women accepted testing (93% vs. 66% of visits); 33% of tests were with clients who had never been tested. EQA results from 29 VHTMs had 100% concordance with the national reference laboratory; three failed due to recording problems. The average quality score was 5.1 out of 7 possible points; 80% scored at least 5. VHTMs reported lack of supplies (49%) and reaching men (26%) as main challenges; 69% were concerned about getting infected. Despite the added service, 91% of VHTMs rated their workload as easy to manage. All VHTMs wished to continue providing HTC, and 91% reported increased work satisfaction.

**Conclusions:** Preliminary results suggest that VHTMs are competent; additional analyses will reveal more on acceptability and effectiveness. Findings will contribute to the evidence base on effective models for expanding quality HTC into communities. This innovative practice has potential for adaptation and scale-up within large-scale CHW systems in sub-Saharan Africa.

**1043 HTC Campaign in Households Reached the Majority of Women But Only 50% of Men in Botswana Community**

Vlad Novitsky1, Hermann Bussmann2, Sikhulile Moyo3, Erik van Widenfelt4, Mompanti Mmalane3, Quanhong Lei3, Joseph Makhem3, Shahin Lockman1, Victor DeGruttola1, Max Essex1

1Immunology & Infectious Diseases, Harvard School of Public Health, Boston, MA, United States, 2Botswana-Harvard AIDS Institute Partnership, Gaborone, Botswana, 3Department of BioStatistics, Harvard School of Public Health, Boston, MA, United States

**Background:** The identification of populations at high risk of HIV infection, or unaware of their HIV status, is a critical component of clinical trials and public health interventions. Better understanding of who the people are who are not covered by provider-initiated HIV-1 counseling and testing (HTC), or household (HH)-based HTC campaigns, could improve strategies aimed to link these individuals to care and reduce rates of onward HIV transmission in communities.

**Methodology:** A baseline and two follow-up enhanced HTC campaigns targeted 16–64-year-old (y.o.) residents in the northeastern sector of Mochudi, a southern African community with 3,650 households. Following community mobilization and engagement, individuals were approached during HH visits and were offered consenting, HIV testing, counseling, data collection and blood sampling. HIV testing was performed in HHs using the Botswana National HIV
Testing guidelines. The data collected during HH campaigns were compared with the United Nations (UN) estimates for the Botswana population stratified by age and gender, and in the context of HIV status.

Results: A total of 6,187 age-eligible residents in the northeastern sector of Mochudi were tested for HIV-1 status in HH, and 1,234 of them were found to be HIV positive. Among those tested in HH, 3,933 were females and 2,254 were males. HIV prevalence rates increased from 3% in males and 5% in females in the age group 16-19 y.o. to 32% in males 40-44 y.o. and 44% in females 35-39 y.o. Comparison with the UN estimates revealed that 88.4% (95% CI 87.5% to 89.4%) of females and 49.5% (95% CI 48.0% to 51.0%) of males aged 16-64 were reached by the HH-based HTC in Mochudi. The proportion of missing men reached 58.8% (95% CI 55.3% to 62.2%) in the age group 25-29 y.o., 63.4% (95% CI 59.6% to 67.1%) in the age group 30-34 y.o., and 61.2% (95% CI 56.6% to 65.6%) in the age group 35-39 y.o. The proportion of missing women was 19.8% (95% CI 16.9% to 23.1%) in the age group 16-19 y.o. and 23.4% (95% CI 20.0% to 27.0%) among women 30-34 y.o. The social and behavior risks of missing populations remain unknown.

Conclusions: The HTC campaign in Mochudi, Botswana, reached 49.5% of men and 88.4% of women in HHs. However the HH-based HTC campaign in Mochudi missed about half of men, and about 12% of women. The proportion of missing men aged 25-39 y.o. was at the level of 60%. To bring the identified age-specific categories of men and women to care and reduce HIV incidence, the identified groups should be targeted by alternative non-standard strategies of HIV testing and counseling in communities.

1044 Implementation of Routine, Opt-Out HIV Testing Does Not Increase Loss To Follow-up

Kate Clouse1, Colleen Hanrahan1, Jean Bassett2, Nandipha Gangule2, Lindi Matjeka2, Sandra Mokonyane2, Ian Sanne3, Annelies Van Rie1

1Department of Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, 2Witkoppen Health and Welfare Centre, Johannesburg, South Africa, 3Right to Care, Johannesburg, South Africa

Background: In 2010, South Africa launched an ambitious national HIV counseling and testing (HCT) campaign. Routine opt-out HCT may impact retention in care, as it is expected to result in a higher proportion of asymptomatic patients with lower levels of immunodeficiency who may not be motivated to seek HIV care. We examined retention in care before and after implementation of routine opt-out HCT at a primary care clinic.

Methodology: In January 2011, Witkoppen Health and Welfare Centre in Johannesburg, South Africa, implemented routine opt-out HCT for all adult (≥18 years) clinic clients with unknown HIV status and those testing negative >3 months ago, regardless of reason for clinic visit. Prior to 2011, clinic clients were tested upon request (voluntary CT), if they accessed antenatal care services, TB services, or if the health care provider requested HCT due to symptoms compatible with HIV infection. We compared patient characteristics and retention in care among clinic clients newly diagnosed with HIV from January-June 2010 (pre-intervention) and February-July 2012 (post-intervention).

Results: In total, 1092 individuals were newly diagnosed during the pre-intervention period and 967 post-intervention. During both periods, median age was 32 years and almost half had immigrated to South Africa from neighboring countries. Most new HIV diagnoses were women (67.2% in 2010 and 65.9% in 2012), but the proportion of pregnant women decreased from 26.6% in the pre-intervention to 16.2% in the post-intervention period (p<0.001). Surprisingly, the median CD4 count at time of HIV diagnosis was similar during both periods: 253 (IQR 128-398 cells/μl) in 2010 and 268 (IQR 139.5-408 cells/μl) in 2012 (p=0.15). The proportion of individuals eligible for ART was 66.7% in the pre-intervention period and 64.1% in the post-intervention period (p=0.21). Within the first 12 months following HIV diagnosis more than half of all individuals newly diagnosed with HIV were lost to follow up: 58.4% during the pre-intervention and 54.6% during the post-intervention. Adjusting for age, CD4 count, gender, pregnancy and nationality, the hazard of LTFU was not impacted by the change in policy (HR 0.97, 95% CI: 0.86-1.09).

Conclusions: Implementation of routine opt-out HCT at the primary care facility level did not increase baseline CD4 count or proportion of people eligible for ART, and did not impact the risk of loss to follow up among those newly diagnosed with HIV. Retention in care after HIV diagnosis, however, was extremely low, with more than half of those newly diagnosed lost to care by one year. To be successful, expansion of HIV testing should be coupled with effective strategies to increase retention in care among those newly diagnosed.

1045 Assessment of the Potential Cost-Effectiveness of HIV Self-Testing in Resource Limited Settings

Valentina Cambiano1, Debbie Ford2, Travor Matugu3, Sue Napierala Mavedzenge4, Alec Miners5, Owen Mugurungi6, Fumiyo Nakagawa7, Paul Reviol8, Andrew Phillips9

1UCL, London, United Kingdom, 2Medical Research Council Clinical Trials Unit, London, United Kingdom, 3University of Zimbabwe Clinical Research Centre, Harare, Zimbabwe, 4RTI International, San Francisco, CA, United States, 5London School of Hygiene and Tropical Medicine, London, United Kingdom, 6Ministry of Health and Child Welfare Zimbabwe, Harare, Zimbabwe, 7University of York, York, United Kingdom

Background: Implementation studies demonstrated that HIV self-testing (ST) is highly acceptable in resource limited settings and could allow savings given its potentially lower implementation cost compared to provider-delivered HIV testing and counselling (HTC). We aimed to evaluate the cost-effectiveness of introduction of ST from 2015 over 20 years in a country such as Zimbabwe.

Methodology: The ‘HIV Synthesis’ model was used to simulate an HIV epidemic similar to the one in Zimbabwe. Simulated age and gender specific rates of HTC for the first time, and repeat HTC fitted approximately to those observed; rates incorporated a 3-fold reduction in rate of testing for people who never had condom-less sex and increased rates of HTC for women attending antenatal clinics and for subjects experiencing symptoms. Sensitivity was assumed to be 92% and 98% and specificity 99% and 100%, for ST and HTC respectively. The cost was assumed to be $3 for ST, $3 for HTC if negative and $25 if positive, or following a positive ST. HTC was required for a person to be diagnosed and it was assumed only 80% of those who had a positive ST would be diagnosed within 1 year as a direct result of the ST. Once diagnosed, linkage to care at 1 year was assumed to be 60% and the same reduction in condom-less sex (13% with long-term partner and 17% with short-term partners declining to 9% after 6 months) was assumed for people testing positive
by HTC or ST. Two main scenarios were considered from 2015. In the reference scenario (RS), ST is not available and the rate of HTC for first time and repeat HTC increases linearly by 0.005 per year. In the intervention scenario (STS), the following effects are assumed: halving of the population not willing to receive a HTC (from 5 to 2.5%), replacing 30% of repeat HTC with ST, replacing 10% of first HTC with ST, and increasing in the rate of repeat testing and of testing for the 1st time by 20%, due to the availability of ST. These assumptions are believed to be conservative in estimating the potential benefits of ST.

Results: We predict the introduction of ST could lead to savings in health care costs of $51 million, while averting around 35,000 DALYS over 20 years in Zimbabwe. Table 1 indicates the most cost-effective scenario under different circumstances.

Conclusions: These results suggest the introduction of ST is cost-effective under most of these assumptions and should be made available. Further work is needed to gather more data to inform modelling assumptions and allow updated evaluations.

1046 Treatment Outcomes Before and After the Decentralization of ART in an Urban Setting in Mozambique

Jan Walter1, Marie-Luce Tombo1, Celeste Gracia Edwards1, Johnny Lujan2, Annick Antierens2, Lucas Mollino2
1Médecins sans Frontières, Maputo, Mozambique, 2Médecins sans Frontières, Geneva, Switzerland

Background: There are few data on the effect of decentralization, task shifting and scale-up on the treatment outcomes of antiretroviral treatment (ART) in Mozambique. We hypothesized that decentralization, task shifting, and scale-up of ART to primary health care centers did not affect the quality of care provided.

Methodology: We compared treatment outcomes and evolution of CD4 cell counts of HIV-infected adults initiated on ART before (2003 to July 2006) with those initiated on ART after (2009-2011) the decentralization ART to primary health care centers in the Chamanculo Health District of Maputo, using routine data. To avoid bias due to changes in referral criteria we included outcomes from an ambulatory referral site in the district, which was created during the decentralization process. We used Kaplan-Meier plots and calculated incidence rates to compare treatment outcomes between groups. We used Poisson regression for adjusted analysis including as possible confounders age, sex, as well as CD4 cell count and WHO stage at treatment initiation.

Results: The study included 3,963 adults initiated on ART before the decentralization and 13,505 adults initiated on ART after the decentralization process had been completed. The overall attrition rate was slightly higher in the decentralized than in the centralized cohort (19.0 events per 100 person years [py], 95% confidence interval [CI]: 17.9 to 20.1 versus 20.4 events per 100 py, 95% CI: 19.8 to 21.0). The reported mortality rate was higher in the centralized than the decentralized cohort (3.6 deaths per 100 py, 95% CI 3.1 to 4.1 versus 1.3, 95% CI: 1.1 to 1.4), as was the rate of transfers (4.1 transfers per 100 py, 95% CI: 3.6 to 4.6 versus 3.3, 95% CI: 3.1 to 3.6), while the rate of loss to follow-up (LTF) was lower in the centralized than the decentralized cohort (19.0 events per 100 py, 95% CI: 17.9 to 20.1 versus 20.4 events per 100 py, 95% CI: 19.8 to 21.0), as was the rate of transfers (4.1 transfers per 100 py, 95% CI: 3.6 to 4.6 versus 3.3, 95% CI: 3.1 to 3.6), while the rate of loss to follow-up (LTF) was lower in the centralized than the decentralized cohort (3.6 deaths per 100 py, 95% CI 3.1 to 4.1 versus 1.3, 95% CI: 1.1 to 1.4), as was the rate of transfers (4.1 transfers per 100 py, 95% CI: 3.6 to 4.6 versus 3.3, 95% CI: 3.1 to 3.6), while the rate of loss to follow-up (LTF) was lower in the centralized than the decentralized cohort (3.6 deaths per 100 py, 95% CI 3.1 to 4.1 versus 1.3, 95% CI: 1.1 to 1.4), as was the rate of transfers (4.1 transfers per 100 py, 95% CI: 3.6 to 4.6 versus 3.3, 95% CI: 3.1 to 3.6), while the rate of loss to follow-up (LTF) was lower in the centralized than the decentralized cohort (3.6 deaths per 100 py, 95% CI 3.1 to 4.1 versus 1.3, 95% CI: 1.1 to 1.4), as was the rate of transfers (4.1 transfers per 100 py, 95% CI: 3.6 to 4.6 versus 3.3, 95% CI: 3.1 to 3.6), while the rate of loss to follow-up (LTF) was lower in the centralized than the decentralized
cohort (11.3 events per 100 py, 95% CI: 10.5 to 12.2 versus 15.8, 95% CI: 15.3 to 16.4). The slightly higher rate of adverse events (death and LTF combined) in the decentralized cohort is explained by the loss of patients directly after the initiation of ART (adjusted incidence rate ratio [IRR] for the first three months: 1.2, 95% CI: 1.1 to 1.3). There was no difference in the rates of adverse events after three months (adjusted IRR: 1.1, 95% CI: 1.0 to 1.2) between both groups. Among patients with available CD4 cell counts, CD4 cell recovery was slightly slower in the centralized as compared to the decentralized cohort, but reached similar values at 2.5 years after treatment start (median 364 cells per μl, interquartile range [IQR] 253 to 494 versus 360 cells per μl, IQR: 254 to 495).

Conclusions: Decentralization, task shifting and scale-up of ART to primary health care centers in the Chamanculo District of Maputo, Mozambique, did not strongly impact the quality of care provided.

1047 CD4 Count at ART Initiation and Economic Restoration in Rural Uganda

Atheendar Venkataramani1, Harsha Thirumurthy2, Jessica Haberer1, Yap Boum1, Mark Siedner4, Annet Kembabazi5, Peter Hunt6, Jeffrey Martin6, David Bangsberg1,7, Alexander Tsai8

1Department of Medicine and Center for Global Health, Massachusetts General Hospital, Boston, MA, United States; 2Department of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 3Epicentre, MSF, Mbarara, Uganda; 4Department of Medicine, Massachusetts General Hospital, Boston, MA, United States; 5Mbarara University of Science and Technology, Mbarara, Uganda; 6University of California San Francisco, San Francisco, CA, United States; 7Massachusetts General Hospital, Boston, MA, United States; 8Department of Psychiatry and Center for Global Health, Massachusetts General Hospital, Boston, MA, United States

Background: Earlier initiation of ART may prevent morbidity driven pre-treatment declines in socioeconomic status and may also influence subsequent economic recovery. We examined associations between CD4 count at time of ART initiation and economic measures both at the start of therapy and during six years of follow-up.

Methodology: Starting in 2005, participants initiating ART at a regional referral clinic in Uganda were enrolled in the Uganda AIDS Rural Treatment Outcomes study (UARTO) and followed prospectively. We collected data on employment and asset ownership annually. Using multivariable regression, we assessed whether economic outcomes at baseline and in the 6 years following ART initiation varied by our primary exposure of interest, baseline CD4 count ≥ or < 200 cells/μL, adjusting for age, gender, education level, and marital status.

Results: We followed 505 individuals for a median of 5 years (IQR 1-7). Participants initiating ART at CD4≥200 (n=179) were more likely to be employed at baseline than those initiating below this threshold (n=327) (0.71 vs. 0.57, p<0.01 for absolute difference, 95% CI 0.06-0.21). Those in the CD4<200 group achieved a similar level of employment within 1 year of initiating ART, and employment rates remained similar throughout the 6 years of follow-up. Both groups had similar asset ownership scores at baseline and demonstrated similar increases in asset scores during follow up.

Conclusions: Those initiating ART at CD4≥200 had higher employment levels at baseline, though those initiating with advanced disease erases the difference within 1 year of therapy. Individuals at all pre-therapy CD4 counts showed significant increases in asset ownership through at least 6 years of therapy. The results suggest that earlier initiation of therapy may help prevent initial declines in employment, though the similarities in baseline asset ownership across CD4 count groups suggests aspects of HIV infection beyond morbidity, such as a reduced propensity to invest in durable assets due to perceived reductions in life expectancy after diagnosis, may impact economic status, as well.

Trends in Employment and Household Asset Scores by CD4 Count at Time of ART Initiation

Notes – Employed = 1 if the individual is employed, hence the mean is the fraction employed. Asset Score ranges from 0-16. Time on ART = 0 refers to pre-ART baseline. CD4 refers to CD4 count at the time of initiation. Only the differences in baseline employment status were statistically significant (0.7 versus 0.57, p<0.01). Standard error bars omitted so as to reduce clutter.
48-Week Outcomes in Adults Starting ART at CD4>350 Using Streamlined Care in Rural Uganda

Vivek Jain1, Dathan M. Byonaneye2, Gideon Amanyire2, Douglas Black1, James Rooney1, Gabriel Chamie1, Elvin H. Geng1, Edwin D. Charlebois1, Moses R. Kamya2, Diane V. Havlir1

1HIV/AIDS Division, University of California, San Francisco, San Francisco, CA, United States, 2Makerere University College of Health Sciences, Kampala, Uganda, 3Gilead Sciences, Inc., Foster City, CA, United States

Background: As WHO guidelines promote earlier ART initiation, there is concern that asymptomatic individuals in Sub-Saharan Africa with high CD4+ counts may not successfully adhere to therapy and achieve virologic suppression. We previously reported high uptake of ART among persons with high CD4+ counts in the EARLI Study (Early Antiretroviral Therapy in Resource Limited Settings in Persons with High CD4+ Counts; NCT:01479634). We report here the 48 week virologic and safety outcomes of EARLI patients with CD4+ ≥350 receiving ART using a streamlined ART delivery model in a prototypic rural Ugandan Health Center.

Methodology: In this open-label study, ART-naïve, HIV-infected Ugandan adults (≥18 years) with CD4+ ≥350 were offered ART (tenofovir/emtricitabine plus efavirenz). Participants were seen by a medical officer at baseline and 4 weeks, and had subsequent nurse visits at 8, 12, 24, 36, and 48 weeks. Safety laboratory evaluations were done at 8, 12 and 48 weeks. HIV RNA levels (viral load) were measured (Abbott) at baseline, 24, and 48 weeks. Undetectable VL was defined as ≤400 copies/mL. Patient self-reported adherence was measured by 3-day recall. Participants did not receive incentives for clinic attendance or adherence, nor appointment reminders.

Results: 200 adults were enrolled; 3 were excluded after baseline HIV status was determined to be negative. Median age was 35 years, 65% of participants were female, median CD4+ count was 564 cells/μL (IQR 448-712), and median HIV RNA level was 22,400 copies/mL. Retention at 48 weeks was 98%. Participants reported high adherence (no missed ART was reported in 1093/1116 [98%] of visits from weeks 4-48). Overall, ART was well tolerated: a total of 22 grade III/IV laboratory abnormalities (DAIDS scale) occurred in a total of 18 participants. The most common abnormality was neutropenia (n=11). Two participants died, one from inoperable gastric carcinoma, and the other from complications following a cholecystectomy. Grade III/IV creatinine elevations occurred in 2/197 participants. In both individuals, tenofovir/emtricitabine was discontinued temporarily and restarted successfully with no subsequent creatinine elevation. The proportion of adults with virologic suppression at 24 weeks was 188/197 (95.4%), and at 48 weeks was 186/192 (96.9%).

Conclusions: 48-week HIV RNA suppression rates exceeded 95% in an open label study of ART in 197 adults with CD4>350 receiving streamlined care in a rural Ugandan clinic. This high CD4+ count population showed robust retention in care, strong ART adherence, and little medication toxicity in a streamlined ART delivery system. These data challenge current views that asymptomatic HIV-infected adults will not be interested or able to comply with ART when initiated at high CD4+ cell counts.

Second-Line Failure and Protease Inhibitor Resistance in a Clinic in Johannesburg, South Africa

Rebecca H. Berhanu1, Denise Evans2, Prudence Iret1, David Spencer1, Cindy Finkhaber1, Ian Sanne1, Matthew P. Fox2

1TB Focal Point, Right to Care, Johannesburg, South Africa, 2Health Economics and Epidemiology Research Office, University of the Witwatersrand, Johannesburg, South Africa, 3Clinical HIV Research Unit, University of the Witwatersrand, Johannesburg, South Africa, 4Helen Joseph Hospital, University of the Witwatersrand, Johannesburg, South Africa, 5Center for Global Health and Development Department of Epidemiology, Boston University, Boston, MA, United States

Background: In resource limited settings, where few options exist for patients failing second line antiretroviral therapy (ART), programmatic approaches to treatment failure must be developed. We report on an approach to standardizing care for patients failing second line in South Africa.

Methodology: We conducted a retrospective study of 314 patients on second line protease inhibitor (PI) ART with a HIV-1 DNA >400 copies/ml at Themba Lethu Clinic in Johannesburg, South Africa between March 2012 and September 2013. Patients underwent adherence counselling and repeat viral load testing. Those with a repeat viral load after re-adherence of >1000 copies/ml underwent testing for HIV-1 drug resistance. If adherence remained a significant problem HIV resistance testing was not done. Sequences were graded as intermediate or resistant using the Stanford University HIV Drug Resistance Database.

Results: Of the 314 patients who underwent adherence counselling, 61% were female. The median age was 40.5 years (IQR 35-47), median CD4 count was 346 cells/mm3 (IQR 205-422) and viral load was 6458 copies/ml (IQR 2044-40006). The average length of time since ART initiation was 5.3 years (IQR 3.2-7.1) and 2.4 years (IQR 1.0- 4.5) on second line therapy. Compared to other patients on second line, patients with treatment failure had lower rates of viral suppression at 6 months (53% vs. 15%) and 12 months (46% vs. 14%) after starting second line.

Of the 314, 282 (90%) had ≥1 repeat viral load, 26 (8%) had none, and 6 patients (2%) died or were lost to follow-up. 166 (59%) achieved viral suppression (<400 copies/ml) over a median (IQR) of 63 days (87-146). 67 of the 282 (24%) had HIV-1 drug resistance tests done of which 21% (14/67) did not amplify. Of the 53 successful tests 45% (24/53) had no clinically significant resistance, 19% (10/53) had NRTI resistance without PI resistance, 17% (9/53) had low level PI resistance and 19% (10/53) had significant PI resistance (Table 1).

In total 19 (6%) patients initiated third line (raltegravir, efavirenz or darunavir). Half of these patients have had repeat viral loads and all are suppressed.

Conclusions: Although most second line failures remain related to adherence and can be overcome with careful counselling, we found that 38% of patients who underwent HIV drug resistance testing had significant NRTI or protease inhibitor resistance requiring third-line treatment. Strategies for preventing second line failure are critical in areas where limited treatment options exist.
1050  A 5-Year Comparison of Viral Load and CD4 Cell Count Monitoring for ART Patients in Rural Uganda

Jonathan Wangisi1, Paul Ekwaru2, Stephen Okoboi3, James Campbell4, Rachel King1, Aggrey Egesa2, Celestine Bakanda1, Emmy Muramuzi2, Frank Kahunza1, Sam Malamba1, David M. Moore1,8

1The AIDS Support Organisation, Kampala, Uganda, 2University of Alberta, Edmonton, AB, Canada, 3University of Maryland, Baltimore, MD, United States, 4University of California San Francisco, San Francisco, CA, United States, 5Makere University School of Public Health, Kampala, Uganda, 6Makere University, Kampala, Uganda, 7BC Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada, 8University of British Columbia, Vancouver, BC, Canada

Background: The Home-Based AIDS Care (HBAC) project was a clinical trial which found no difference in clinical outcomes between participants who were randomized to viral load (VL) monitoring and CD4 cell count monitoring in comparison to CD4 cell count monitoring alone after 3 years of follow-up. We further report on clinical outcomes from this study with an additional 2 years of follow-up.

Methodology: Beginning in May 2004, HIV-infected members of The AIDS Support Organisation (TASO) - Tororo with a CD4 count of <250 cells/mm3 or WHO Stage 3 or 4 disease were offered ART and randomized to one of three monitoring groups: Arm A) Clinical monitoring and quarterly CD4 cell counts and VL; Arm B) Clinical monitoring and quarterly CD4 cell counts; or Arm C) Clinical monitoring alone. Field workers delivered ART to participants’ homes and collected data to monitor potential toxicity, morbidity and mortality. In April 2007, following analysis of the first phase of the study which demonstrated that Arm C participants were at increased risk for death and/or new opportunistic infections (OIs); these individuals were re-randomized to Arms A or B and all participants were followed until March 31, 2009. Clinical events prior to re-randomization in Arm C patients were not included in this analysis. We conducted bivariate analyses of clinical and demographic characteristics of study participants in the remaining two arms and used Cox Proportional Hazard models to determine if study arm was independently associated with the development of OIs or death.

Results: A total of 1012 participants (73.7% female) were randomized to one of the 3 original study arms and of these, 316 survivors from Arm C were re-randomized to Arms A and B. The median age was 38 years and the median CD4 cell count at enrollment was 134 cells/mm3. 509 individuals were followed in Arm A/C and the 503 in Arm B/C for a median of 4.4 years of follow-up. There were no significant differences in clinical or sociodemographic characteristics between two groups at randomization or re-randomization. Over the entire length of the study, 38 deaths and 20 new OIs occurred in Arm A patients and 36 deaths and 21 new OIs occurred in Arm B patients. Randomization to Arm B was not associated with the risk for new OIs or death (adjusted hazard ratio [AHR] = 1.03; 95% CI 0.75 - 1.43). We also found no effect on randomization when we excluded the original Arm C patients (AHR = 0.97; 95% CI 0.68 - 1.39).

Conclusions: We found no differences in clinical outcomes associated with the addition of quarterly VL monitoring to quarterly CD4 cell count monitoring. These data continue to support expanding access to ART in resource-limited settings, irrespective of the availability of VL testing.

1051  Success of Transfer of HIV Care From a PEPFAR Site To Community-Based Clinics in South Africa

Christie Cloete1, Susan Regan2,3, Janet Giddy1, Tessa Govender1, Melanie B. Gaynes2, Kenneth A. Freedberg3,4, Jeffrey N. Katz4,5, Rochelle P. Walensky3,6, Elena Losina3,7, Ingrid V. Bassett3,4

1McCord Hospital, Durban, South Africa, 2Massachusetts General Hospital, Department of General Medicine, Boston, MA, United States, 3Massachusetts General Hospital, Medical Practice Evaluation Center, Boston, MA, United States, 4Bingham and Women’s Hospital, Department of Orthopedic Surgery, Boston, MA, United States, 5Division of Infectious Diseases, Massachusetts General Hospital, Boston, MA, United States, 6Boston University School of Public Health, Departments of Biostatistics and Epidemiology, Boston, MA, United States, 7Division of Infectious Disease, Massachusetts General Hospital, Boston, MA, United States

Background: PEPFAR funding changes have resulted in HIV clinic closures, necessitating the transfer of large cohorts of patients to government-funded, community-based clinics. We evaluated linkage to care following a rapid, large-scale transfer of patients from a hospital-based HIV clinic in South Africa.

Methodology: All adult (≥18y) patients on ART who visited the hospital-based HIV clinic in Durban from March to June 2012 were transferred to >170 clinics. Hospital counselors identified patients’ target transfer clinic based on their home location and care needs. Study staff surveyed subjects 5-10 years following transfer to their home clinic or hospital to identify critical events of interest.

Results: A total of 1012 participants (73.7% female) were randomized to one of the 3 original study arms and of these, 316 survivors from Arm C were re-randomized to Arms A and B. The median age was 38 years and the median CD4 cell count at enrollment was 134 cells/mm3. 509 individuals were followed in Arm A/C and the 503 in Arm B/C for a median of 4.4 years of follow-up. There were no significant differences in clinical or sociodemographic characteristics between two groups at randomization or re-randomization. Over the entire length of the study, 38 deaths and 20 new OIs occurred in Arm A patients and 36 deaths and 21 new OIs occurred in Arm B patients. Randomization to Arm B was not associated with the risk for new OIs or death (adjusted hazard ratio [AHR] = 1.03; 95% CI 0.75 - 1.43). We also found no effect on randomization when we excluded the original Arm C patients (AHR = 0.97; 95% CI 0.68 - 1.39).

Conclusions: We found no differences in clinical outcomes associated with the addition of quarterly VL monitoring to quarterly CD4 cell count monitoring. These data continue to support expanding access to ART in resource-limited settings, irrespective of the availability of VL testing.

Methodology: We further report on clinical outcomes from this study with an additional 2 years of follow-up.

Results: A total of 1012 participants (73.7% female) were randomized to one of the 3 original study arms and of these, 316 survivors from Arm C were re-randomized to Arms A and B. The median age was 38 years and the median CD4 cell count at enrollment was 134 cells/mm3. 509 individuals were followed in Arm A/C and the 503 in Arm B/C for a median of 4.4 years of follow-up. There were no significant differences in clinical or sociodemographic characteristics between two groups at randomization or re-randomization. Over the entire length of the study, 38 deaths and 20 new OIs occurred in Arm A patients and 36 deaths and 21 new OIs occurred in Arm B patients. Randomization to Arm B was not associated with the risk for new OIs or death (adjusted hazard ratio [AHR] = 1.03; 95% CI 0.75 - 1.43). We also found no effect on randomization when we excluded the original Arm C patients (AHR = 0.97; 95% CI 0.68 - 1.39).

Conclusions: We found no differences in clinical outcomes associated with the addition of quarterly VL monitoring to quarterly CD4 cell count monitoring. These data continue to support expanding access to ART in resource-limited settings, irrespective of the availability of VL testing.
months after transfer to assess self-reported linkage to the target clinic. To examine the validity of self-report, we randomly selected 8 clinics from the 80 clinics closest to the hospital for record reviews. We estimated the overall success of transfer as a weighted average of linkage to care for subjects reached and not reached for the survey, adjusted for results of the validation visits.

Results: Of the 4,690 patients who visited the HIV clinic in the year prior to its closure, 3,927 (84%) were transferred and phoned at least once. Mean age was 40 years (SD 9.3); 59% were female, and most recent CD4 prior to transfer was 375/μl (IQR 251-530). Of transferred patients, 3,384 (86%) were reached and completed the survey; 3,376 (99.8%) reported attending a transfer clinic. Of those reached, 866 (26%) reported visiting a different clinic than that assigned. The most common reasons for attending alternative clinics were: told by the receiving clinic to go elsewhere (23%), stigma concerns (16%), and inconvenient location (14%). Among the 756 patients assigned to the 8 validation clinics, 659 (87%) were reached for the survey. 531 (81%) of those surveyed reported going to their assigned clinic. Among those who self-reported attending their assigned clinic, 446 (84%) had a visit validated in the clinic record. Of the 46 people who self-reported attending a validation clinic to which they were not originally assigned, 39 (85%) had a validated visit. Of the 97 patients who could not be reached for the survey, 59 (61%) had a validated visit at their assigned clinic. Based on the validation rates for reached, self-reported, and unreached patients, the estimated success of transfer for the cohort overall was 81%.

Conclusions: A large majority of patients reported successful transfer from a hospital- to a community-based clinic in South Africa, though a quarter of patients attended a different clinic than assigned. Validation of self-reported attendance at a clinic highlights that nearly 20% of patients may not have linked to care. Efforts to optimize transfers to community sites require accurate contact details and collaboration with receiving clinics to ensure successful linkage to care.

1052 The Feasibility and Economic Impact of Time Designated Appointment System in a Busy HIV Care Clinic

Zachary A. Kwena1, Betty Njoroge2, Patrick Oyaro1, Craig R. Cohen3, Elizabeth A. Bukusi4
1Center for Microbiology Research, Kenya Medical Research Institute, Kisumu, Kenya, 2Center for Microbiology Research, Kenya Medical Research Institute, Nairobi, Kenya, 3Ob/Gyn & RS, University of California, San Francisco, San Francisco, CA, United States

Background: As efforts are made to put the remaining 40% of people in Kenya on HIV treatment, the problem of congestion at HIV care clinics is likely to worsen. Averting the likely negative impact of this problem require instituting new measures to improve overall patient flow. We evaluated the feasibility and the economic benefits of a time designated appointment system as a solution to decongest a large HIV care and treatment clinic in Kisumu, Kenya.

Methodology: This was a two arm open label randomized controlled trial recruiting 354 patients at Lumumba Health Centre in Kisumu, Kenya, a large urban HIV care and treatment clinic supported by Family AIDS Care and Education Services (FACES). Consenting participants were enrolled during their normal clinic days and followed up at subsequent clinic appointments for up to 12 months. Intervention arm participants were given specific dates and times to come to the clinic for their next appointment. In comparison, control arm participants were given the date to come for the next appointment and had full discretion to decide on the time to arrive as is the standard practice in Kenya. All participants reported at the study office for arrival and departure time clocking and to respond to a brief follow up questionnaire. The study was designed to fit into FACES clinic schedules and procedures with minimum interruption. All clinicians at the site took care of study participants as part of their normal workflow. To get valuation of the work participants were involved in on their clinic day, we asked them the nature of the work they did before and after their clinic appointment and how much they would pay if they were to hire someone to do the work for them.

Results: Nearly two thirds (60.7%) of the participants were women with a mean age of 37 (standard deviation [SD] 9). About 87% of participants were on antiretroviral treatment. The most recent mean CD4 count was 548 (SD 233). In all the visits in the intervention arm combined, 72.1% of the participants arrived on time, 13.3% arrived ahead of time and 14.6% arrived past scheduled time. Participants in the intervention arm spent less time at the clinic [1.8 hours (SD 1.1)] compared to control [3.2 hours (SD, 1.2) (p<0.001)]. Furthermore, participants enrolled in the intervention arm were more productively engaged on their clinic days valuing their work at USD 3.3 (SD 3.1) compared to control participants who valued their work at USD 2.6 (SD 2.1) (p=0.017).

Conclusions: Time designated appointment system in HIV care clinics is feasible and provides substantial time savings, and was associated with greater economic productivity for HIV patients at a busy HIV care and treatment clinic. Further research is required to determine if a time designated appointment system is scalable, and functions well in other settings.

1053 Long-Term Virologic Response in a Cohort of HIV-Infected Patients in South Africa

Kate Shearer1, Alana T. Brennan1, Mihai Maskev1, Rebecca Berhanu2, Lawrence Long1, Matthew Fox1,2
1Health Economics and Epidemiology Research Office, Johannesburg, South Africa, 2Center for Global Health & Development, Boston, MA, United States, 3Right to Care, Johannesburg, South Africa

Background: While much is known about virologic response to antiretroviral therapy (ART) in resource-rich settings, much less is known about long-term rates of virologic suppression in resource-limited settings. We aimed to describe virologic response on ART over 8 years among a cohort of patients initiating ART the first year of the public sector roll out in South Africa.

Methodology: We included all ART-naïve patients, ≥18 years, who initiated first-line ART from April 2004-March 2005 at 4 public sector HIV treatment clinics in Gauteng and Mpumalanga Provinces. Patients were followed from ART initiation until death, transfer, loss to follow-up (LTF) or dataset close (May 2013). LTF was defined as being 3 months late for a scheduled visit with no subsequent visit. Virologic suppression was defined as a viral load (VL) 1000 copies/ml. A transient elevated viral load (TEV) was defined as a failing VL followed by a suppressed VL.
Results: 2357 patients were included. 68.8% were female with a median (IQR) age of 35.4 (30.5-42.0) years and a median (IQR) baseline CD4 count of 80 (34-141) cells/mm³. Patients were followed for a median (IQR) of 6.2 (2.1-8.3) years. At the end of follow-up, 18.0% of patients had died, 24.4% of patients were LTF, and 30.1% of patients had transferred.

1912 (81.1%) patients had ≥1 VL recorded with a median (IQR) of 11 (6-14) VLS over the duration of follow-up. Of those, 96.0% (n=1835) achieved virologic suppression and 68.4% (n=1255) of those patients suppressed on their first VL. Among those 1255 patients, 53.2% remained suppressed at every subsequent VL (median: 11; IQR: 6-13). For the 535 patients who did not remain suppressed, patients experienced a median (IQR) of 2 (1-3) detectable VLS and the first detectable VL occurred in a median (IQR) of 2.7 (1.1-6.1) years after the first suppressed VL (Figure).

704 (36.8%) patients experienced ≥1 TEV and were less likely to die (7.7%) or become LTF (15.6%) compared to patients who never experienced a TEV (death: 13.1%; LTF: 23.0%), potentially due to increased monitoring of patients experiencing adverse virologic response.

Conclusions: Long-term suppression is common in this cohort of HIV-infected individuals. However, over 70% of patients left the cohort (died, transferred, or left care) by the end of follow-up. Further research is needed to determine successful interventions for retaining patients in care in order to ensure continued success of the ART program in South Africa.

1054 CD4 Cell Decline and Time To Reaching ART Eligibility in HIV Patients From Rwanda
Chloe A. Teasdale, Allison Zerbe, Veronica Mugisha, Ruben Sahabo, Elaine J. Abrams, Wafaa M. El-Sadr, for Identifying Optimal Models of HIV Care in Africa Study
ICAP, Columbia University, New York, NY, United States

Background: CD4 cell count thresholds are a key parameter used for assessing antiretroviral therapy (ART) eligibility. Determining the rate of CD4 decline is important in estimating the impact of different CD4 thresholds for ART initiation and for establishing monitoring frequency for patients not eligible for ART. Few data are available on CD4 decline in HIV-infected patients in resource limited settings. We analyzed the rate of CD4 decline in ART-naïve adults in Rwanda and assessed time to reaching ART eligibility as per 2010 and 2013 WHO guidelines.

Methodology: We examined CD4 decline in HIV-infected patients >15 years with CD4>600 cells and at least one follow-up CD4 prior to ART initiation enrolled from 2005-2010 at 41 Rwandan health facilities supported by ICAP-Columbia University. CD4 decline in the first 24 months was estimated using mixed linear regression modeling. Competing risk estimators were used to assess time to reaching ART eligibility at CD4<350 or CD4<500, accounting for loss to follow-up, death and ART initiation as competing risks.

Results: We analyzed data for 4,643 patients with a median age of 32.1 years [Interquartile range (IQR): 25.9-40.1], 73% female, 65% with WHO stage 1 at enrollment and median pre-ART
follow-up time of 21.4 months. Median and mean CD4 at enrollment were 773.0 [IQR: 676-923] and 830.1 [IQR: 676-923], respectively. Mean CD4 counts were significantly lower among men (-38.6, 95% CI 25.1-52.1, p<.0001) and patients >40 years of age (-20.9, 95% CI 7.1-34.7, p<.01). The average CD4 decline over 24 months of follow-up was 5.3 cells/month (95% CI 5.0-5.6) and 63.6 cells by 12 months (95% CI 60.2-67.0). No significant difference was observed in the rate of CD4 decline for men compared to women, however patients >40 years of age had a CD4 decline of 10.8 more cells per year (95% CI 3.0-18.6, p<.01). By 24 months, 11.1% (95% CI 10.1-12.1%) of patients reached CD4 < 350 and 33.0% (95% CI 31.4-34.5%) reached CD4 < 500. Among patients with CD4 600-800 cells at enrollment, less than half (45.9%, 95% CI 43.7-48.1) reached CD4 < 500 and 15.0% (95% CI 13.3-16.4) reached CD4 < 350 in 24 months of follow-up.

Conclusions: In this large cohort of ART-naïve HIV patients from Rwanda with CD4 > 600 cells, average CD4 decline was estimated to be 63.6 cells/year, a very similar rate to that found in resource-rich settings. One third of patients reached ART eligibility within 24 months using current WHO guidelines of CD4 < 500 and only 11% reached CD4 < 350 cells as per 2010 WHO guidelines.

**1055 Predictors of Late Engagement To HIV Care in Western Kenya: A Cross-Sectional Study**

Charles M. Kwebah1, 2, Paula Braitstein3, 4, Julius Koch5, Gilbert Simiyu6, Ann W. Mwangi2, 3, Kara Wools-Kaloustian2, 6, Abraham Sika2, 6

1Medicine, Moi University Clinical Research Centre, Eldoret, Kenya, 2Academic Model Providing Access to Healthcare, Eldoret, Kenya, 3Medicine, Moi University College of Health Sciences, School of Medicine, Eldoret, Kenya, 4University of Toronto, Dalla Lana School of Public Health, Toronto, ON, Canada, 5Behavioural Sciences, Moi University College of Health Sciences, School of Medicine, Eldoret, Kenya, 6Medicine, Indiana University School of Medicine, Indianapolis, IN, United States

**Background:** Late patient presentation contributes significantly to the high mortality reported in HIV-care and treatment programs in sub-Saharan Africa.

**Methodology:** To assess the factors associated with late engagement we conducted a cross-sectional study using data extracted from the electronic medical records system of the Academic Model Providing Access to Healthcare (AMPATH). AMPATH provides HIV treatment across 80 clinics in western Kenya. Data from all the 80 clinics were included in this analysis. Patients were eligible for analysis if they were > 14 years and enrolled between 1st December 2010 and 31st December 2012. Late engagement was defined as an enrollment CD4 count ≤ 100/μl. Analysis was conducted using a Chi-Square test of associations between categorical/dichotomous variables, a T-test comparison of group means and a multivariable logistic regression model to assess risk factors associated with late engagement.

**Results:** Of the 10,533 participants included in the analysis, 67% were female; mean age 36.7 years (sd 11.0) and median baseline CD4 cell count was 258 cells/μl (IQR 111,437). Overall, 2,421 (23%) of the participants presented with baseline CD4 cell count ≤ 100/μl. Median time to ART initiation was 28 days (IQR 14 to 44). Factors associated with late engagement included male gender (AOR: 1.57, 95% CI: 1.38-1.78); older age (AOR: 1.02, 95% CI: 1.01-1.03); longer travel time to clinic (AOR: 1.23, 95% CI: 1.09-1.39); being employed (AOR: 1.21, 95% CI: 1.06-1.39) and having tuberculosis (AOR: 3.10, 95% CI: 2.71-3.54).

**Conclusions:** Nearly one-quarter of HIV infected patients in our setting present with advanced immune-suppression at initial encounter. Being male, older in age, employed, living further away from clinic and having tuberculosis are associated with late engagement to care. There is an urgent need to identify innovative ways to engage males in testing, test in the workplace and ensure that TB clinics are testing for HIV at presentation into care.

**1056 Cost Savings of Viral-Load Testing Before ART Second-Line Switch in a Resource-Limited Setting**

Joanita Kigozi1, Christine Mugasha1, Alex Muganza2, Alex Coutinho1, Yukari Manabe2

1Infectious Disease Institute, Kampala, Uganda, 2Johns Hopkins University, Baltimore, MD, United States

**Background:** WHO guidelines for patients on antiretroviral therapy (ART) recommend immunologic monitoring when viral load (VL) testing is not available. In sub-Saharan Africa immunologic monitoring is neither sensitive nor specific and leads to switching to second-line regimens that are more costly than first-line ART. We sought to determine if VL testing in patients suspected of immunologic failure was cost-saving.

**Methodology:** We reviewed the records of patients who had VL testing prior to ART switching as recommended by the existing program in 7 government-run urban clinics in Kampala, between October 2008 and October 2011. VL testing was performed in an unsubsidized central lab facility where the cost of a VL test is $62. The cost of first-line ART averaged $14.68 per person per month and second-line ART, $35.99 per person per month.

**Results:** 312 patients were tested at 7 clinics in Kampala City. 185 (59%) had detectable VL (>400 copies/mL) and 127(41%) had undetectable VL (<400 copies). Of the 185 with detectable VL, 24 had 5000 (51.6%) were switched to second-line while 151 patients with VL < 5000 (48.4%) remained on first-line therapy. The cost of targeted VL testing in patients with immunologic failure was recouped in 6.0 months when compared to the increased cost of treating patients who had immunologic failure but suppressed VL with the second line regimen as indicated in table 1.

**Conclusions:** Testing with VL prevents the unnecessary switching to second-line ART in 50% of patients and recouping of the cost of VL testing in those who immunologically fail at 6.0 months.

1057 Peer Support and Engagement, HIV Care and Sexual Behaviors Among PLHIV Not On ART: A Randomized Trial
Larry W. Chang1,2, Gertrude Nakigozi2, Veena Billioux2, David Serwadda2, Thomas Quinn3, Robert Bollinger1,2, Maria Wawer2, Ronald Gray4, Steven Reynolds4
1Johns Hopkins School of Medicine, Baltimore, MD, United States; 2Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States; 3Rakai Health Sciences Program, Entebbe, Uganda; 4Laboratory of Immunoregulation, Division of Intramural Research, National Institute for Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, United States

Background: People living with HIV (PLHIV) not on antiretroviral therapy (ART) benefit from engagement in care, preventive care interventions, and decreasing risky sexual behaviors. Peer support may be an economical intervention to facilitate these issues in an integrated approach. We conducted a randomized trial on the impact of peer support on HIV care and prevention outcomes among PLHIV not on ART in Rakai, Uganda (The PeerCARE or Peer Community-based Assistant in Retention and Engagement Study).

Methodology: Participants recently identified as HIV-infected by the Rakai Health Sciences Program (RHSP) but not on ART were randomized to peer support or standard of care. Peer support consisted of monthly home visits to reinforce engagement in care, preventive care interventions (cotrimoxazole prophylaxis, bednet, and safe water vessel use), and safer sexual behaviors (using condoms and decreasing partners) based upon an Information, Motivation, and Behavioral Skills conceptual framework of behavior change. Standard of care was referral to local RHSP clinics. Patients were administered an end of study survey assessing key outcomes after one year of follow-up. Log binomial regression with robust standard errors were used to calculate prevalence risk ratios (PRR) with 95% CIs.

Results: 447 participants were enrolled and followed June 2011-July 2013 (225 intervention; 222 control). Baseline characteristics were balanced: median age was 30 (IQR 27-37); 64% were female; 62% had previously visited an RHSP clinic; 45% had already initiated cotrimoxazole prophylaxis. After a median follow-up of 363 days (IQR 352-378), 87% of intervention and 90% of control participants completed the end of study survey (p=0.33). As shown in the Table, intervention participants were more likely to be in care, have initiated cotrimoxazole prophylaxis, and be adherent to safe water vessel use. No effects were observed on ART initiation or sexual behaviors. Most of the attributable effect was among participants with no history of prior linkage to RHSP clinics (see Table, n=151).

Conclusions: Patients randomized to a peer support were more likely to remain in care, initiate cotrimoxazole prophylaxis, and be adherent to safe water vessel use at one year of follow-up. This effect was mostly seen in patients not previously linked to RHSP care. No effects were observed on ART initiation or sexual behaviors. Peer support may be an effective intervention to address care and prevention needs of PLHIV not on ART.

1058 Community-Based ART Programs in Resource-Limited Settings
Stephen Okoboi1, Ding Erin1, Steven Persaud2, Jonathan Wangisi3, Darius Katevi3, Chen Yalini3, Maureen Nonyinomo3, Celestine Bakanda4, Josephine Birungi5, David Moore5,4
1Research, The AIDS Support Organization, Kampala, Uganda; 2Research, British Columbia Centre for Excellence in HIV/AIDS, Vancouver, BC, Canada; 3Faculty of Medicine, University of British Columbia, Vancouver, BC, Canada

Background: Patients in ART programs in rural African settings are challenged by the high costs of transportation which can lead to high rates of loss-to-follow-up (LTFU) and death. We examined program retention among long-term patients of an ART program in rural Uganda which has used a community-based distribution of ART and satellite clinics since its inception in 2004.

Methodology: We conducted a retrospective cohort analysis of all patients >18 years who initiated ART at TASO-Jinja between January 2004- July 2009. We identified all clients in community and facility-based ART delivery arms using an electronic clinical monitoring database. The catchment area included participants in villages up to 75kms away from Jinja town. Enrollees were expected to attend regular clinic or outreach visits every one- to- three months.
CD4 cell count testing was offered every six months. We calculated the proportion of participants who had at least one recorded clinic or outreach visit in the six months before June 2013 and examined associations with the combined outcome of LTFU or death using Cox proportional hazards model.

**Results:** A total of 3345 participants began ART during 2004 - 2009 and the median time on ART in June 2013 was 5.69 (IQR=4.10 - 7.23) years. Of these, 2380 (71%) were females, the median age was 40 years (IQR=34-46) and the median CD4 count at initiation was 184 cells/μL (IQR=95-298). A total of 1335 (40%) were residents of Jinja district and 2005 (60%) resided in outlying districts. Of these, 2322 (69%) were retained in care, 577 (17%) died, 161 (5%) transferred out, 285 (9%) were LTFU. Factors associated with mortality or LTFU included male gender (adjusted hazard ratio [AHR]=1.56 95% CI 1.28-1.9), CD4 cell count<50 (AHR=4.09; 95% CI. 3.13 -5.36) or 50 - 199 cells/μL (AHR = 1.86 ; 95% CI 1.46 - 2.37) ART initiation , WHO stage 3 (AHR=1.35 ; 95% CI 1.1 - 1.66) or 4 (AHR=1.74 ; 95% CI 1.23-2.45) illness; initiating ART on D4T,3TC and NVP (AHR=1.37 ;95% CI 1.08 -1.75 ) and year of ART initiation (AHR = 1.32; 95% CI 1.20 - 1.46). Notably, residence outside of Jinja district was not associated with mortality/ LTFU(AHR = 0.87; 0.71, 1.05)

**Conclusions:** Among participants enrolled in an ART program for a median of over 5 years, rates of mortality and LTFU were very low and did not differ based on the geographic residence of program participants. This suggests that community-based distribution systems can effectively mitigate the time and cost constraints associated with transportation to ART clinic sites.

**The Treatment Cascade and Loss To Follow-Up**

**1059 Gender Differences in Loss To Follow-up and Mortality in Older Adults On ART in Sub-Saharan Africa**

*Mansi Agarwal1, Matthew R. Lamb1, Veronica Kugitha2, Davies Kimanga3, Bonita Kilama1, Andrea A. Howard1, Elaine J. Abrams1, Wafaa M. El-Sadr1, Batya Elul1*

1ICAP-Columbia University, New York, NY, United States, 2National AIDS and STI Control Programme, Nairobi, Kenya, 3National AIDS Control Programme, Dar es Salaam, Tanzania, United Republic of

**Background:** People living with HIV (PLWH) ≥50 years of age are a growing but understudied population in Sub-Saharan Africa. Gender differences in outcomes after ART initiation have been well documented for PLWH aged 15-49 years but less is known about older PLWH. We explored the effect of gender on loss to follow up (LTF) and recorded mortality after ART initiation among PLWH aged ≥50 years.

**Methodology:** We used routinely collected patient-level data from PLWH ≥50 years initiating ART at 199 HIV health facilities supported by ICAP-Columbia University in Rwanda, Tanzania, Mozambique and Kenya. Age was categorized in 5 year increments. PLWH were considered LTF if they had no record of death or transfer and did not have a recorded clinic visit for 6 months. Cox Proportional Hazard Models examined gender differences in LTF and mortality 12 months after ART initiation in three ways: (1) across all age groups; (2) stratified by age; and (3) stratified by gender. All models controlled for disease status (CD4+ <100cells/mL or WHO stage 4 vs. CD4+ ≥100 cells/mL or WHO stage 1-3) at ART initiation, point of entry into HIV care (i.e. in-patient ward vs. all other entry points), and country.

**Results:** From 2005-2011, 21,634 PLWH aged ≥50 years (median (IQR): 55 years (52-59)) initiated ART; 50% were 50-54 years, 26% 55-59 years, 14% 60-64 years, 6% 65-69 years, and 4% ≥70 years of age. Across all ages, men had significantly higher rates of LTF (HR: 1.23, 95% CI: 1.13-1.34) and death (HR: 1.38, 95% CI: 1.24-1.53) compared to women at 12 months after ART initiation. When stratified by age, this gender difference remained significant only among PLWH aged 50-59 years (see table). Stratification by gender showed LTF increased for men aged 60-69 years compared to those aged 50-54 years. For women, LTF was similar across all ages except for the oldest (≥70 years), where the rate was higher than women aged 50-54 years. Mortality rates increased with age among both men and women.

**Conclusions:** Our study extends prior research that men aged 15-49 years on ART have worse outcomes than women by showing that this gender differential holds among patients aged 50-59 years. Interestingly, this gender difference is lost among PLWH aged 60 years and older in our study. These results imply that future research and interventions addressing poor outcomes among men on ART should include older patients, at least through age 59.

**Comparative Effectiveness of HIV Care and Treatment Programs in East Africa**

Elvin Geng1, Thomas Odeny2, Rita Lyamuya3, Alice Nakikwoga-Muwanga4, Mwebesa Bwana5, Paula Brattstein6, Andrew Kambugu6, Elizabeth Bukusi7, Geoffrey Soni7, Lameck Diero8, Jeffrey Martin9

1Medicine, University of California San Francisco, San Francisco, CA, United States, 2KEMRI, Nairobi, Kenya, 3Medicine, NACP, Dar es Salaam, Tanzania, United Republic of, 4IDI, Kampala, Uganda, 5Medicine, MUST, Mbarara, Uganda, 6AMPATH, Eldoret, Kenya, 7Medicine, KEMRI, Nairobi, Kenya, 8NACP, Dar es Salaam, Tanzania, United Republic of, 9University of California San Francisco, San Francisco, CA, United States

**Background:** Survival after initiation of antiretroviral treatment (ART) among HIV-infected patients in Africa is a critical measure of the effectiveness of the public health response. Regional differences in mortality, after adjustment for biological factors (e.g., pre-therapy CD4 value), would suggest that the behavior of health care systems and patient populations play an important role in effectiveness. In routine program settings, however, high loss to follow-up (i.e., unknown outcomes) is common and many deaths are not ascertained.

**Methodology:** We evaluated HIV-infected adults on ART in five HIV care programs in Kenya, Uganda and Tanzania. Socio-demographic and clinical data were recorded during routine care on standardized forms issued by respective Ministries of Health. To manage the effects of loss to follow-up, we intensively traced a random sample of patients without unknown outcomes (defined as at least 90 days late for last visit) in the community. Outcomes in this sample of traced patients were incorporated into survival analysis using probability weights to revise estimates of mortality.

**Results:**

- Over two years, we followed 33,947 adults on ART: 15,613 from Kenya program 1; 4,844 from Kenya 2; 2,615 from Uganda 1; 7,532 from Uganda 2 and 3,343 from Tanzania 1. The median age was 35 years (IQR: 29-42), 66% were women, median pre-therapy CD4 count was 155/μl (IQR: 70-237). Overall, 5,801 (25%) were lost to follow-up and of these, 980 (17%) were randomly selected for tracking and vital status was ascertained in 89% of the 980. Using only deaths known to programs before tracing, the two-year cumulative incidence of mortality was 2.4% (95% CI: 2.3%-2.6%). Incorporating outcomes among the lost led to a revised estimate of 7.5% (95% CI: 6.9%-8.1%). After adjustment for age, sex, pregnancy, whether patient was new to clinic at observation start, pre-therapy CD4 value, and tuberculosis at ART initiation, the clinical care program of the patient remained associated with mortality. Using Kenya program 1 as reference group, the adjusted hazard ratio for death in Kenya 2 was 1.04 (95% CI: 0.78-1.38), in Uganda 1 was 1.36 (95% CI: 1.0-1.84), in Uganda 2 was 0.56 (0.38-0.79) and in Tanzania 1 was 1.91 (95% CI: 1.46-2.52).

**Conclusions:** After accounting for biological drivers of mortality, program-to-program differences in survival on ART remain substantial. Even within the standardized and simplified public health approach to HIV treatment effectiveness may vary. Understanding regional variability in health delivery (e.g., quality, patient-centeredness) and patient behavior (e.g., engagement, adherence) is needed to optimize HIV treatment in Africa.

**1061 Loss To Follow-Up: Determining Outcomes for Adults Enrolled in HIV Services in Kenya**

William Reidy1, Mansi Agarwal1, Matthew Lamb1, Mark Hawken1, Duncan Chege1, Batya Elul1, Elaine J. Abrams1, Elvin Geng2

1Mailman School of Public Health, ICAP-Columbia University, New York, NY, United States, 2School of Medicine, University of California at San Francisco, San Francisco, CA, United States

**Background:** Loss to follow-up (LTF) from HIV programs can present a barrier to effective evaluation of patient outcomes, such as death, and may be misinterpreted as an indicator of engagement in care. We used data from defaulter tracing for a random sample of patients LTF in one PEPFAR-supported HIV clinic to correct death estimates and estimate true disengagement from care for the larger population from which the sample was derived.

**Methodology:** Patients of the HIV clinic at Gatundu District Hospital in Kenya with at least 1 clinic visit between 2008-12 were assessed for LTF status using electronic data, with LTF defined as no visit in the past 3 (ART) or 6 (pre-ART) months and not dead or transferred-out. Of these, a random sample, stratified by pre-ART and ART status, was selected for study tracing. Tracers tracked patients and completed a questionnaire for patients or contacts found, collecting information including patient vital status (alive/dead) and engagement in care (in care/disengaged). Rates and percent dead and in care were presented using the initial clinic data and data updated with outcomes from defaulter tracing, weighted to represent all patients LTF. Patients reported by a contact as alive were classified as in care (optimistic scenario) or disengaged (pessimistic scenario) in separate analyses.

**Results:** 413 (21%) of the 1,974 clinic patients were LTF, of which 66 (16%, 40 pre-ART, 26 ART) were sampled. Questionnaires were completed for 65 (98%) patients (46 patients, 19 contacts). Seven (18%) pre-ART and 6 (23%) ART patients reported being disengaged from HIV care. Nine (23%) pre-ART and 5 (19%) ART patients were reported to have died. Updating the initial data with sample outcomes increased overall retention in care for pre-ART patients from 61% to 69% (pessimistic) or 75% (optimistic) and for ART patients from 84% to 88%; deaths increased from 10% to 18% for pre-ART patients and from 8% to 10% for ART patients. Incidence rates for death were lower and for LTF/disengagement substantially higher in the initial data than in the updated data, for both pre-ART and ART patients (see table).

**Conclusions:** This suggests that only a minority of patients classified as LTF by one large HIV clinic in Kenya are actually disengaged from HIV care. Also, death rates were underestimated. While our data are from a single facility, these findings suggest that high levels of LTF observed in routinely-collected data may be a poor proxy for disengagement from care and obscure higher death rates.
1062 Community ART Delivery for High Patient Retention - TASO Uganda Operational Research
Denis Mpiima1, Birungi Josephine1, Luzze Ceaser2, Nnafuka3 Masitula2
1Medical, The AIDS Support Organisation, Kampala, Uganda, 2Medical, International Health Sciences University, Kampala, Uganda, 3Programmes and Strategic Information, The AIDS Support Organisation (TASO), Kampala, Uganda

Background: The AIDS Support Organization (TASO) implements a mixture of ART service delivery models (facility, home and community models since 2005. An increasing numbers of ART lost to up, 1433 (6.4%) and 1498(6.7%) deaths from a cohort of 23235 was noted between 2000 to 2009. Community drug distribution points (CDDPs) were started to improve ART retention and adherence among clients on the programme. Little has been known about structural interventions that can sustain very good ART adherence and retention of patients into the ART. A study to assess and compare adherence and retention out comes from the community and facility ART delivery models was conducted.

Methodology: Analytical retrospective study by design. Data collection was electronic data review for all registered TASO Jinja clients who have been on ART for the period above two months by July 2010. Uni-variates and bi-variates analysis was done. A comparison of outcomes was done using the chi-square test. Retention was based number of patients reported not lost to follow up and dead while on ART. Good adherence was defined as taking ART doses at 95% and above of the prescribed treatment. P- Value < 0.05 was considered to statistically significant for the study.

Results: A total of 3457 clients were studied with 1055(30.5%) males and 2402(69.5%) females.1302 (37.65%) were facility based and 2155(62.35%) CDDPs based. Loss to follow-up was four times higher in the facility arm with 215(16.5%) of 1302 patients compared to 103(4.28%) of 2155 CDDP clients, p=0.074 for facility clients. Fewer deaths were reported in the CDDP arm 84(3.9%) compared to facility with 77(5.7%), p=0.008.

Conclusions: Community drug distribution points (CDDPS) model has better patient retention outcomes evidenced by four times reduction in lost to follow up. CDDPs is a good retention approach especially for health facilities with high volume ART clinics supplementing the traditional facility based model.

1063 HIV Care Cascade Among Hard To Reach Populations in India: Need To Expand HIV Counseling and Testing
Shruti H. Mehta1, Gregory M. Lucas2, Sunil Solomon1, Aylur K. Srikrishnan3, Allison McFall1, P. Nandagopa1, Pachamuthu Balakrishnan1, Muniratnam S. Kumar1, David D. Celentano1, Sunil S. Solomon1, 2
1Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, 2Johns Hopkins University School of Medicine, Baltimore, MD, United States, 3YR Gambonde Centre for AIDS Research and Education, Chennai, India

Background: Early identification of HIV infection, prompt linkage to care, retention, initiation of ART and suppression of viral load (VL) are critical steps along the HIV care cascade. Hard-to-reach groups such as injection drug users (IDUs) and men who have sex with men (MSM) tag behind at each step, particularly in low-and-middle-income settings where access challenges are complicated by stigma and discrimination. We characterize the spectrum of engagement in HIV care for IDUs and MSM in India.

Methodology: We recruited 12,022 MSM and 11,897 IDUs across 27 cities in India (target=1000 per site) using respondent-driven sampling from 10/2012 - 9/2013. Participants had to be 18 years old, self-identifiy as male and report sex with a man in the prior year (MSM) or report injection drug use in the prior 2 years (IDU). All participants underwent a survey and blood draw. HIV was diagnosed using double ELISA. We report the median of site-level proportions of each outcome along with 10th and 90th percentiles.

Results: 1150 MSM were HIV-infected with prevalence across sites ranging from 2 - 15%. Among those infected, a median 44% were diagnosed, 40% linked to care, 34% retained (saw provider in prior 6 months), 30% initiated on ART and 24% had suppressed VL. However, there was tremendous variability across site (percent diagnosed range: 0 - 92%; suppressed VL range: 0 - 59%). 2534 IDUs were HIV infected with prevalence across sites ranging from 5 - 47%. Among those infected, a median 36% were diagnosed, 32% linked to care, 25% retained, 20% were on ART and 15% had suppressed VL. Similar variability across site was observed (percent diagnosed range: 3 - 92%; suppressed VL range: 0 - 46%). Factors significantly associated with diagnosis in both groups included older age, larger network size, more education, and a history of tuberculosis. Among MSM, diagnosis was also significantly associated with being married, being a receptive partner and history of a sexually transmitted infection. Among IDUs, diagnosis was also significantly associated with a history of opiate substitution.

Conclusions: In this large sample of MSM and IDUs across India, the major barrier to successful engagement in HIV care was diagnosis, with fewer than 50% having been diagnosed. Overall, engagement was...
better in sites with higher HIV prevalence where there have been more government-led targeted interventions. Efforts should focus on improving access to HIV testing for these groups in all settings by linking HIV testing to other essential services.

1064 Unplanned Interruptions in HIV Care in Nigeria: Rates and Implications
Aima A. Ahonkhai, Bolanle Banigbe, Juliet Adeola, Heyinwa Onwuchukwu, Ingrid V. Bassett, Elena Losina, Kenneth A. Freedberg, Propser Okonkwo, Susan Regan

Background: Unplanned care interruptions pose a challenge to effective HIV treatment. However, little is understood about rates of interruptions and how to minimize interruptions in care in resource-limited settings. Our objective was to determine the frequency, risk factors, and impact of unplanned care interruption on virologic outcomes among HIV-infected patients in Nigeria.

Methodology: We conducted a retrospective cohort study at a university-affiliated HIV clinic in Nigeria. The cohort included adults (≥14yrs) who enrolled in care and initiated ART between January 2009 and December 2011. Follow-up was through December 2012. We defined unplanned care interruption as a period in which patients had no contact with the HIV clinic for clinical, laboratory, or ART pick-up visits. We studied interruptions of >3 months, > 6 months, or any interruption (>3 or > 6 months). We used multivariate logistic regression models adjusted for observation time to measure associations between baseline clinical and demographic factors with having at least one care interruption. We assessed HIV RNA levels at return to care in those with unplanned interruptions.

Results: Among the 2,496 patients in the cohort, 69% were female, median age was 32 years and 8% were students. In the 1st year on ART, median days between clinic visits was 30. Over 90% of all visits involved drug-pick-up. Thirty-seven percent of patients had ≥1 care interruption lasting at least 3 or 6 months. Sixteen percent of patients had one 3-month interruption, 10% had one 6-month interruption, and 11% had combinations of both. Rates of interruption were highest in the 1st year on ART (28.4/100PY), and declined with each year on ART [Figure 1]. In multivariate analysis, students (OR1.6, p = 0.025), those with baseline CD4 >350/uL (OR2.7, p<0.0001), and those with any hospitalization during follow-up (OR1.6, p = 0.020) were at increased risk for any interruption of 3- or 6-month duration. On return to care, 49% of those with 3-month and 61% with 6-month interruptions had HIV RNA >1,000 copies/ml.

Conclusions: Nearly 40% of all patients starting ART in a large treatment program in Nigeria had interruptions in care of 3 or 6 months. Interruptions occurred most commonly in the 1st year on ART, and were associated with loss of virologic suppression. Students, those with high baseline CD4 count and those hospitalized during the follow-up period were at highest risk. Focused interventions in the 1st year on ART are essential to ensure continuity of HIV care.

1065 Using the Side Door: Non-Linear Patterns Within the HIV Treatment Cascade in Zambia
Charles B. Holmes, Angela Bengtson, Izukanji Sikazwe, Carolyn Bolton-Moore, Lloyd B. Mulenga, Patrick Musonda, Benjamin H. Chi

Background: Although the HIV care and treatment cascade has typically been portrayed as a linear process starting from HIV testing and counseling to treatment and retention, patients may actually be dropping out of care and re-entering at a later time. We sought to characterize this “side door” phenomenon in a large public health program in Zambia among adults who initiated antiretroviral therapy (ART).

Methodology: Our analysis cohort comprised treatment-naïve, HIV-infected adults (≥15 years) initiating ART in 18 Lusaka sites Jan. 2002 - Feb. 2008, including follow-up for their first 3 years on ART. Individuals were divided into 3 groups based on outcomes at 3 years post-ART initiation: 1) remaining on treatment, 2) >60 days late for a scheduled visit but not returning, and 3) >60 days late for a scheduled visit but “re-presenting” into care. Baseline characteristics for the 3 groups were compared and frequency of re-presentation was enumerated. A multivariable logistic model was constructed among those lost to follow-up (LTFU), with a dependent variable of re-presentation/continued loss and covariates including baseline characteristics.
Results: 48,126 patients were included, median age 34 years (IQR 29, 41), 61% women, and median initiation CD4: 132 (IQR 66, 205). Among those >60 days late for a scheduled visit (n=28,417), 65.4% never returned, 27.8% had 1 re-presentation episode, 5.3% had 2 re-presentation episodes, and 1.3% had 3 representation episodes. Average period of loss before first re-presentation was 105 days (SD 161), and median 35 days (IQR 10, 124). Re-presenting patients were less likely to have CD4<200 cells/mm3, WHO stage 3/4, and anemia (Hemoglobin (Hb) <8 g/dL) at baseline ART initiation.

Conclusions: Re-presentation after initial loss to follow-up is common in an urban HIV treatment cohort in Zambia and is more likely in healthier individuals. This is one of the first empiric characterizations of this important phenomenon in ongoing HIV care and treatment efforts, and one that should be considered in the design of future interventions for program retention and monitoring.

1066 Effectiveness of Potential Improvements in the Cascade of HIV Treatment and Care in South Africa

Valentina Cambiano1, Silvia Bertagnolio2, Michael Jordan1, Jens Lundgren3, Alec Miners4, Deenan Pillay5, Paul Revill5, Francois Venter6, Andrew Phillips1

1UCL, London, United Kingdom, 2WHO, Geneva, Switzerland, 3University of Copenhagen, Copenhagen, Denmark, 4London School of Hygiene and Tropical Medicine, London, United Kingdom, 5University of York, York, United Kingdom, 6University of the Witwatersrand, Johannesburg, South Africa

Background: Implementation studies demonstrated that it is possible to substantially reduce the leakages at different steps of the cascade of care. Our aim is to evaluate the effectiveness of potential improvements in each step and of changing the eligibility criteria to initiate ART (EC) in South Africa.

Methodology: The ‘HIV Synthesis’ model calibrated to South Africa was used. By the end of 2013 it is assumed 62% of the population ever tested for HIV, 29% in the last year, 71% are linked to care (LK) by 1 year since diagnosis, 42% of those not eligible at staging are retained in pre-ART care (RPC) at 1 year, EC is CD4<350 cells/μ, 84% are retained on ART (RA) at 1 year since initiation and the median time to switch to 2nd line after virological failure is 12 months. The maintenance of this status is referred to as R. The following improvements, implemented over 2014 and 2015, are considered: EC of CD4<500 cells/μ (F), EC at diagnosis (D), increase in HIV testing so that 85% ever tested for HIV (T), reduction in loss at diagnosis so that 85% are LK (L), improvements in pre-ART retention, so that 72% are RPC (P), improvements in retention on ART, so that 92% are RA (A), reduction in the time to switching to 2nd line to 5 months (S). In addition the following combination of the above are considered: improvement in T with change in EC to CD4<500 cells/μ (TF) and at diagnosis (TD); improvement in LK and RPC with EC respectively CD4<350 cells/μ (LP), <500 cells/μ (LPF) and at diagnosis (LPD); as LP with improvement in HIV testing and on ART (TLPA); as TLPA with EC at CD4<500 cells/μ (TLPAF) and at diagnosis (TLPAD); improvements at all steps with EC at CD4<350 cells/μ (TLPAS), <500 cells/μ (TLPASF) and at diagnosis (TLPASD).

Results: The single improvement which leads to the highest increment in life-years over 20 years is the improvement in retention on ART (7.6 million), which leads to the greatest reduction in deaths among HIV+ (930,000). Modifying the EC to initiate ART at diagnosis saves the highest number of HIV infections (760,000), but results in an increment in lifeyears of 3.5 million. Improvements at all steps of the cascade allow gaining over 15 million life-years over 20 years.
Conclusions: Our modelling helps to understand which interventions will have the biggest impact on maximising life years, and shows that improving retention on ART has the greatest impact. Cost-effectiveness analysis could help to identify which interventions would represent value for money from limited health sector resources.

Session P-X4 Poster Session
Wednesday March 5, 2014, 2:30 pm–4:00 pm  Exhibit Hall D
Mental Health in HIV Care

1067 Trends in Depression Among Patients Presenting for ART in Rural Uganda
Brian T. Chan 1, 2, Sheri D. Weiser 3, 4, Yap Boum 5, Jessica Haberer 6, Annet Kembabazi 7, Peter W. Hunt 7, Jeffrey N. Martin 8, David R. Bangsberg 8, Alexander C. Tsai 8, 6
1Infectious Diseases, Massachusetts General Hospital, Boston, MA, United States, 2Harvard Medical School, Boston, MA, United States, 3Center for AIDS Prevention Studies, University of California San Francisco, San Francisco, CA, United States, 4Division of HIV/AIDS, University of California San Francisco, San Francisco General Hospital, San Francisco, CA, United States, 5Epicentre, Mbarara, Uganda, 6Center for Global Health, Massachusetts General Hospital, Boston, MA, United States, 7Mbarara University of Science and Technology, Mbarara, Uganda, 8Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA, United States

Background: Among people living with HIV (PLHIV), depression has been associated with poorer HIV-related outcomes, including increased transmission risk, poorer ART adherence, and more rapid CD4 decline or progression to AIDS and death. Little is known about trends in depression at ART initiation among PLHIV in low- and middle-income countries (LMICs) during the early years of expansions in access to ART. We used data from the Uganda AIDS Rural Treatment Outcomes (UARTO) study, an ongoing cohort of treatment-naïve PLHIV begun in 2005, to estimate secular trends in depression among PLHIV at ART initiation and to understand the factors explaining these trends.

Methodology: A linear regression model was fitted to the baseline data with depression symptom severity, measured using a locally adapted version of the Hopkins Symptom Checklist (HSCL-D), as the outcome variable and year of cohort entry (2005-2012) as the explanatory variable. We adjusted our estimate using baseline socio-demographic characteristics (age, gender, educational attainment, marital status, household asset wealth, and employment status). Next, we assessed physical health score and CD4 count as potential mediators of the secular trend in depression symptom severity by adding the variables of interest to the model and re-assessing the statistical significance of the regression coefficient for year of entry.

Results: 498 persons with complete data, including 355 women (71.3%), were included in the models. 140 (28.1%) respondents had HSCL-D scores consistent with probable depression (women, 34.7% vs. men, 11.9%; p<.001). A linear regression model revealed a statistically significant negative association between year of entry into cohort and HSCL-D (b = -.04; 95% CI, -.06 to -.02) at entry, suggesting a 2.5% relative decline in the mean depression symptom severity score at ART initiation in each year of study recruitment after the first year. After inclusion of baseline socio-demographic characteristics, the adjusted regression coefficient for year of entry remained statistically significant. The addition to the model of physical health score, but not CD4 count, caused a reduction in magnitude and loss of statistical significance for the regression coefficient for year of entry (b=-.014; 95% CI, -.034 to .007).

Conclusions: Mean depression severity scores at ART initiation declined over time among PLHIV in a rural Ugandan cohort. This secular trend appeared to be explained by better physical health at ART initiation. Secular improvements in depression at ART initiation may be related to ART being initiated among patients with better physical health, which warrants further study and may provide an important further rationale for earlier ART initiation in LMICs.

1068 Mental Health and Mortality in an HIV Treatment Cohort in Rural Uganda
Alexander C. Tsai 6, Brian T. Chan 1, Yap Boum 2, Jessica E. Haberer 1, Annet Kembabazi 2, Peter W. Hunt 3, Jeffrey N. Martin 4, David R. Bangsberg 1
1Massachusetts General Hospital, Boston, MA, United States, 2Medicins San Frontieres, Mbarara, Uganda, 3University of California San Francisco, San Francisco, CA, United States, 4University of California San Francisco, San Francisco, CA, United States

Background: Depression has been associated with systemic immune activation and increased mortality in HIV+ persons. The only study in sub-Saharan Africa to examine the depression-mortality relationship was conducted among HIV+ women who lacked access to HIV antiretroviral therapy (ART). To address this gap in the literature, we used data from an ongoing HIV cohort in rural Uganda to determine the extent to which the depression-mortality relationship holds among HIV+ persons initiating ART.

Methodology: Beginning in 2005, treatment-naïve HIV+ men and women were enrolled into the Uganda AIDS Rural Treatment Outcomes cohort at the
time of treatment initiation. Participants completed bloodwork and structured questionnaires at pre-treatment baseline and quarterly thereafter. Baseline depression symptom severity and mental health-related quality of life were measured using locally adapted versions of the Hopkins Symptom Checklist (with a score >1.75 indicative of probable depression) and MOS-HIV mental health summary. Vital status was ascertained through participant tracing in the event of missed study visits. We fit Cox proportional hazards regression models, adjusting our estimates for baseline age, sex, marital status, educational attainment, household asset wealth, CD4+ T-lymphocyte cell count, body mass index, and MOS-HIV physical health summary.

**Results:** Of 694 participants, 480 were women (69%), and pre-treatment median baseline values were: age, 34 years (IQR, 28-40); CD4 count, 162 (IQR, 91-249); depression score, 1.4 (IQR, 1.2-2.0); and MOS-HIV mental health summary score, 53 (IQR, 47-59). 216 participants (31%) met screening criteria for probable depression. Over 4.3 median years of follow-up, only 48 participants (7%) were lost to follow-up and there were 44 deaths. After multivariable adjustment, probable depression was associated with increased mortality (AHR=2.24; 95% CI, 1.08-4.62), while mental health-related quality of life was not (AHR=0.98; 95% CI, 0.94-1.03).

**Conclusions:** Depressed mood is associated with increased mortality among HIV+ persons initiating ART. Screening for depression may be a relatively low-cost method of identifying HIV+ persons at high risk for mortality. Whether pre-ART depression reflects underlying immune activation or poor overall health status should be addressed in future studies.
